The emergence of the Japanese as effective competitors in many consumer and producer product markets dates back to before World War II. In the last three decades of the nineteenth century, Japan had begun to develop the competency to produce tradable goods, primarily through the purchase of foreign know-how and technology. By the 1920s, in several key sectors, Japan was second if not the first in the world in terms of exports (Glasmeier et al., 1993). Although cut off from international trade in the 1930s, Japan continued to build up its productive capacity until just before the declaration of war. This time the emphasis was placed on heavy and chemical industries.

The emergence of collective capitalism as a distinct mode of organization is both a creature of history and a more modern institutional form. At the end of World War II, Japan had little choice but to pursue an export-led development strategy (McCraw, 1986; Samuels, 1994). The country lacked resources and had a small land base with a large population. In order to stave off poverty and economic despair, the nation had to develop export competencies in a variety of sectors. For reasons that can only be understood retrospectively, the Japanese did not choose to pursue products that were labor intensive despite its large labor force; rather, it moved rapidly into capital-intensive production as part of economic recovery in the 1950s.

The second major stimulant in the formation of collective capitalism was in part a holdover of the structure of the national economy that had developed since the beginning of the twentieth century. Japan's economy is composed of interlocking business organizations that enjoy both vertical and horizontal affiliations. Furthermore, the system of integration reaches down to the level of select blue-collar workers in first-tier firms who are offered lifetime employment in return for a life of dedication to the firm. In this way, guaranteed their jobs, workers willingly accept technological change as a part of labor–management relations.

Although many distinctions are attributable to the Japanese system, of particular importance is the role of the enterprise groups – networks of firms – that form the modern-day extensions of the *zaibatsu*, the family-controlled businesses that led the development of the Japanese economy from the end of the nineteenth century until the US occupation after World War II. These enterprise groups consist of a central business firm around which reside vast numbers of both affiliate and nonaffiliate subcontractors. This disintegrated system allows the core firm to enjoy the benefits of vertical integration, especially in terms of financing, technology transfer, and internal markets, without the disadvantages of ownership and bureaucratic control. The core firm is able to ensure quality, quantity, and timely and effective delivery of parts and services due to long-term contracts and investments made by the core firm into subcontracted operations (Lazonick, 1991).

The emergence of collective capitalism is essential in understanding the industrial geography of the early twenty-first century. Along with recognition of differences in the organization of industry, there was increasing interest in how culture – defined as the rules and practices, identities, and aspirations of individuals at the most intimate level – helps to shape economic space. Throughout the life of an industry, different conventions and rules of behavior form the basis for collective action. Organizational behavior and prevailing institutional norms structure the range of possibilities of firms and regions. This interaction forms the industrial landscape. Observers began to focus on elucidating the importance of culture as a determinant of corporate behavior and the ways culture manifests within people, which in turn shapes firms within regions (Schoenberger, 1997).

The role of culture in the diffusion of the industrial landscape became clearer as developing nations asserted their

positions as industrial powerhouses. Since the late 1980s, select countries in the Global South have experienced significant growth in manufacturing scope and export capacity. Countries such as South Korea and Taiwan over 30 years pursued strategies based on industrial upgrading and explicit price setting to achieve industrial policy targets, and exploited second-mover advantages to become supply chain leaders in increasingly sophisticated products including cell phones, advanced machine tools, and computer products. In contrast to the model of industrial supply chains composed of myriad small firms, Taiwanese industrialization took the form of gigantic vertically integrated firms of the likes of Foxcom, the singular supplier of many of Apple's most coveted products. South Korea and China among others have followed similar paths in their quest to become dominant global suppliers.

Each country's path to integration in the world economy has been distinct, varying by the direction of state-led policy and access to critical assets. After the collapse of the Soviet Union, Russia leveraged its vast natural resources, specifically in oil and gas, to rebuild its wealth despite its troubled transition away from a centrally planned economy. Brazil also benefitted from access to raw materials in advancing its steel industry, but since the stabilization of its economy in the mid-2000s, national leaders have turned their attention to strengthening industrial policies that have served the country well in the past. Low wages are facilitating the expansion of India's labor-intensive manufacturing sectors, although the country's initial transition from an agrarian society centered on noncapital-intensive industries of a service nature. Challenges related to infrastructure and land access hinder the speed of India's industrialization. China has built its economic dominance on its reputation as 'the workshop of the world,' focusing its state-driven efforts on maximizing exports and import substitution while placing restrictions on direct investment. Other emerging players, such as South Africa, are building on their strengths and attracting the attention of profit-seeking multinational corporations.

The Existence and Importance of the Creative Economy

Starting in the 1960s, increasing global competition in product markets, dramatic advances in information sharing and technology, and ongoing mechanization and outsourcing of traditional manufacturing jobs in industrialized countries accelerated the evolution of the knowledge economy. Industries using knowledge as a factor of production and those that created knowledge-intensive goods became key drivers of economic growth. One result of this shift was a change in the skill profiles that employers were seeking in both developed and emerging economies. Firms began to move away from the standardized and easily transferrable competencies of the assembly line and toward the tacit – unspoken or implicit – knowledge required for technology-heavy and highly interpersonal work.

At the turn of the century, the discussion of the knowledge economy narrowed to the concept of creativity as an economic growth engine. Richard Florida (2002) is credited for bringing the economic importance of creative workers to the forefront of popular dialogue. His 'creative class' broadly consisted of those developing new ideas and innovative materials in fields ranging from science and engineering to arts and entertainment. As the most critical input of production for the twenty-first century, theory dictated that the urban areas most effective in drawing employees from this class would increase their chances for successful development. City leaders quickly embraced strategies associated with constructing and promoting the amenities prized by creative workers. This approach was particularly enticing for declining industrial locations looking to recover from devastating losses of middle-class manufacturing employment.

The emphasis on creativity expanded to the global context, motivating some countries to adopt national policies that enhanced their appeal to creative industries, firms, and employees. Measures of creativity became a barometer for evaluating growth potential, and intergovernmental organizations advocated bolstering the creative economies of developing nations to provide income and employment while promoting social equity (United Nations, 2013). Cities ranging in scale from Rio de Janeiro to Kuala Lumpur have implemented interventions designed to encourage creativity and innovation (Evans, 2009).

Despite the vigorous transfer of creativity policies among cities across the globe, these approaches have not benefited all adherents equally (Peck, 2005). In a manner reminiscent of their traditional industrial predecessors, agglomerations of creative industries display patterns of geographical unevenness based on existing humans, built environment, and natural resources. Not all cities are able to parlay their assets into a setting attractive to a footloose sector of society not always uniform in its tastes. Concentrations of creative firms tend to form in urban areas that have well-developed horizontal producer networks, a diversified labor market with a mix of high- and low-skilled workers, and a culture supporting seamless knowledge exchange (Scott, 2006). Determinants of these critical elements are often associated with cities' historical functional specializations and locational endowments.

Today's industrial landscape is thus the sum of long-evolving processes, the residue of which is reflected in the structure and formation of business enterprises, industrial clusters, and systems of industrial activity. In this way, industrial geography is not only the study of a physical place per se but also an examination of the reservoir of experiences and actions that come to represent actors in a locality and its economy.

Abstract

In a society of individuals and of globalization, is the already-old US concept of industrial relations still valid? Is collective bargaining compatible with flexibility and competitiveness? On the other side, does it take into account stress and suffering at work or the social costs of unemployment? This article first makes the point that different types of industrial relations systems have developed: Britain, continental Europe, and the USA-plus-Japan model. Then it shows that wage-earners have always had various ways of expressing themselves within firms and in the public sphere. Trade unions are only one of them. Unions, which have recently undergone a severe crisis almost everywhere, cannot be stable partners, as was initially argued in the USA, but they remain significant whenever they consider the diversity of the labor force and the interests not only of the firm but of society at large. Therefore the recent critiques of the concept of industrial relations require us to revisit it.

In most developed countries, wages and working conditions, forms of employment, bonuses, and allowances are regulated, either by law or by collective agreements. The latter are themselves bordered by juridical or customary rules which define their beginning, process, and results. Their coherence does not merely reflect the logic of the national institutions and of the economy. It takes into account the social actors themselves and the aggregation of their decisions, which constitute industrial relations systems. They vary throughout the course of history. They also differ amongst North America, Japan, and Europe and within Europe itself. But everywhere these systems have been deeply altered or even challenged since the 1980s.

The Concept of Industrial Relations

The term 'industrial relations' was born in the USA. It is the product of both changing relations between companies and wage-earners and of academic attempts to instil some order into the turmoil of social change.

Commons

John R. Commons, an economist at the University of Wisconsin (Madison), produced, during the first third of the twentieth century, the first major interpretation of social relations in 'American industrial society.' He argued that US workers were more wage-conscious than class-conscious. If companies became aware of these fundamental tendencies, there was room for contracts between management and trade unions. Conflicts could be avoided, minimized, or solved. Government was welcome to promote economic growth by supporting the contractualization of industrial relations. Commons and his followers stressed the importance of institutions for organizing society. Accordingly, they considered trade unions to be a source of social progress. They privileged collective bargaining as fitted to US exceptionalism and adapted to unionization by trade, not by industry.

Commons and his followers were not pure and simple academics. They actively contributed to the liberalization of US social legislation which developed between 1918 and 1940.

Dunlop

John T. Dunlop, a sociologist at the University of Wisconsin, working between the 1950s and the 1970s, went further in the same direction. He systematized the idea of systems of industrial relations at local, regional, or national levels. Thus he stressed the interdependence between the key elements of industrial relations: for instance, between the definition of a trade union, its representativity, and the nature of a negotiation. This interdependence is characterized not only by a common juridical doctrine, but also by reciprocal strategies carried out by managers and unions. Moreover, rules in industrial relations need to be interpreted by reference to the policies of unions, companies, and trade associations. Social actors create rules and bind each other by such regulations, at least for a specific period of time. Like Commons and his followers, Dunlop and his colleagues worked as experts for public administrations and played a significant part in the evolution of collective bargaining and of legislation till the first oil crisis. Unlike Commons, they moved from the idea of US exceptionalism to its apparent opposite: a possible universal convergence between the national systems of industrial relations. 'Industrialism' would bring about a civilization of social relations everywhere by generating stable processes of collective bargaining. Meanwhile, Dunlop recognized the plurality of national and continental systems.

Three Models in Europe

At the end of the nineteenth century and during the twentieth, Europe developed specific features in its industrial relations systems, which are still in force. Collective bargaining is first and foremost the responsibility of employers' associations and trade unions by trade or sector, coordinated by confederations. Bargaining at company level came later, is growing, but remains under the aegis of federations. A distinction is made between collective bargaining, which deals mostly with wages and working time, and participation of wage-earners, which includes work conditions, welfare, and the adaptation of a broader collective agreement to a firm; also, more recently,

information on the firm's strategy and its impact on employment. In Germany, participation extends to codetermination, introduced under the Weimar Republic and generalized in the aftermath of World War II, by laws passed in 1951–52. Governments are involved in the national regulation of industrial relations. Intra-European variety may be reduced to three types of patterns. The patterns are quite different on other continents.

The UK and the Republic of Ireland

This is the oldest industrial relations system. Trade unions are closely related to trades and collective bargaining is basically at the level of the firm or the workshop. Conversely, strikes are frequent at this level, yet they do not foster political radicalization. Labour legislation is light. Politics and society tend to privilege the freedom of action of employers and unions.

Central and Northern Europe

This group comprises Germany, Austria, Switzerland, and the Scandinavian nations. It is characterized by a trend towards uniqueness in several forms: uniqueness of employers' associations – powerful, structured, obeyed; uniqueness of trade unions – strong and connected to political power; uniqueness of social conflicts – abiding in written or implicit rules. Collective bargaining is centralized by branch. So are strikes, limited to the period of negotiation. In these countries government intervenes by legislating on industrial relations. However, employers and unions have moved to restrict its interference. The Netherlands and Belgium may be included in this group, although both have a plurality of trade unions.

The Latin Countries

This group covers France, Italy, Spain, Portugal. The keyword here is pluralism: pluralism of conflicts, with a significant percentage of preventive strikes and of wildcat strikes; pluralism of trade unions, with a pole of socialist origin, another of Christian origin, and one which calls itself autonomous or independent; pluralism of political influences among wage-earners. In addition, there is limited authority and even, for many years, pluralism of employers' organizations themselves. Collective bargaining long proceeded only at the national level (for one branch or for the general economy), except at the end of local strikes. Bargaining at company level became a more regular practice in the mid-1950s or even later. Government regulates a variety of issues, except in Italy.

North America and Japan

North America

The US labor movement long featured a pluralism of organisations (in fact till 1955), and employers were as reluctant as elsewhere to negotiate with unions. Things changed with the New Deal. The 1935 Wagner Act, however deeply modified by the 1947 Taft–Hartley Act, made collective bargaining a right for employees, but a union had to be accredited by the vote of a majority of them as the sole counterpart of management in collective bargaining. Law deemed collective bargaining to progress 'in good faith,' i.e., to aim at an agreement. Thanks to the sitdown strikes of the mid-1930s, bargaining spread all over the USA and its contents broadened. The areas of bargaining are now wages, working hours, and work conditions. They may include other matters which have consequences for these elements. The closed-shop clause has been declared illegal. As for Canada, it generally followed the US trends.

Japan

Up to Japan's defeat at the end of World War II, collective bargaining was exceptional in Japanese companies and would materialize only at the end of strikes. Practices and legislation changed in the late 1940s, under the influence of Japanese liberals and US occupying forces. Collective bargaining became a constitutional right for wage-earners. A company has to bargain with any union which asks for it, and even with any group of employees which does not constitute a union, provided it can express a common will. The employer must present counterproposals to the demands of the employees and negotiate 'loyally.' The contents of collective bargaining are extremely broad. A wave of strikes enabled both the spread of unions and of collective bargaining in postwar Japan. However, radical unions were finally defeated; worker activism and protest gave way to management victory in the 1960s and 1970s. Company unions took the upper hand in pursuit of economic affluence. Collective bargaining became a type of cooperation with management, and often quite an influential one. This evolution laid the foundations for a corporate-centered society.

In North America and in Japan, when there is no union in the workplace or no agreement is reached, the rights of the employee may be in fact minimal and management keeps its unilateral powers.

Recent Changes

The End of an Era

Many authors consider the stages reached by national industrial relations systems after World War II to have been parts of social settlements built after the strains of the international economic depression of the 1930s and of the wars of the early 1940s, paving the way for a new era of growth. When growth decelerated in the time of oil crises in the 1970s, when national tariff barriers were lowered, and neoliberal ideas made a spectacular headway in the West, industrial relations systems came under attack. At the same period in a number of countries, though not all, membership of unions started to decline. The breakdown of the population changed from a majority of blue-collar workers to an increasing proportion of white-collar employees, in keeping with a growing proportion of women at work and a shift from industry to services. Unemployment simultaneously rose.

A Shift in Industrial Relations

On a world scale, trade unions entered an era of concessions to employers in terms of wages. The flexibility of work conditions

grew. Mechanisms of social protection weakened. Companies moved to a greater individualization of wages, careers, even contracts, and to a more intense involvement of each employee in the workplace. Integration quite often became their motto. Japan was the last country to undergo this new trend and to try and adjust to the challenge. In many countries militancy and the yearly number of strikes and strikers declined. Yet both large companies and governments stressed the importance of collective bargaining to accompany such far-reaching changes and to stabilize the emerging global competitive order. In some countries ways were found to integrate small and medium-sized enterprises in industrial relations systems. Outside the USA the reduction of working time became a target for collective bargaining and legislation. In each country some of the trade unions began to adapt and modernize their strategies and structures. Some were able to regain members in new working groups. But altogether their societal position has not yet been stabilized and the balance between individual and collective has been altered in significant aspects, in favor of the former.

Current Debates

The Impact of New Practices on the Paradigm

These changes in industrial relations themselves have caused new debates among scholars about Dunlop's paradigm. The development of framework agreements, of agreements on discussion methods, of agreements setting a policy and targets rather than rights, in short of agreements which are not contracts, is quite different from the explicit forms and the strict obligations characterizing most of collective bargaining in the USA during the 1950s and the 1960s. Collective actors appear less neatly defined, more unstable, and the representativity of unions is under redefinition in some countries. In short, actors may become more defined by action itself. A number of scholars argue that such developments do not invalidate Dunlop's paradigm, as it is based on autonomous actors able to create rules and to keep their word.

Recurrent Critiques

Simultaneously older critiques of the paradigm find a greater audience. A number of authors have stressed the importance of unorganized conflict, expressed by absenteeism and turnover. They also stress that the US model of the social conflict as a simple form of adjusting industrial rules may reduce its dimensions and that trade unions are not everywhere limited to the provision of personal services to wage-earners. These authors doubt the possibility of a convergence of national industrial relations systems, despite the development of multinational companies and of continental economic unions. Is it still so easy to say that these systems are functional to industrialization? Are the frontiers of these systems clearly defined, as they indeed produce part of their economic or technological 'context' themselves? Are they not less stable than their earliest analysts implied? What are the multiple sources of their dynamics? Therefore, research on industrial relations is coming back on the agenda of social sciences, as well as of organizations and of individuals.

Industrial Societies

Alf Hornborg, Lund University, Lund, Sweden

Abstract

The concept of 'industrial society' is generally used for a type of social organization based on mass production of commodities. This type of societies began to dominate Western Europe toward the end of the eighteenth century, reflecting a strategy to expand export production in order to appropriate embodied labor and resources from elsewhere in the world-system. Perceived as progress and 'development,' this transition has shaped hegemonic worldviews and visions of a desirable future for all humankind, but current concerns with inequalities, resource depletion, and climate change suggest that such aspirations are not globally sustainable. Industrialization and urbanization tend to fundamentally transform sociocultural conditions and human–environmental relations. Anthropological perspectives can illuminate how the cultural inclinations and self-representations of industrial societies are geared to global political economy, sociology, and ecology.

The concept of 'industrial society' is generally used for a type of social organization that emerged in Western Europe after the so-called Industrial Revolution toward the end of the eighteenth century. It has affinities with concepts such as 'modernity' and 'capitalism' and is often thought of as based on Enlightenment ideals of rationality and progress. As it tends to reflect a cultural self-representation of economically affluent or 'developed' nations, the concept deserves critical cultural analysis and needs to be contextualized in time and space. This article approaches the phenomenon of industrial societies through the macro-level perspectives of world history, political economy, and global ecology, while indicating how a cultural critique rooted in anthropology can complement the accounts of history and sociology.

World-Historical Prerequisites

Industrial societies are often contrasted against 'preindustrial,' generally agricultural societies with regard to fundamental economic strategies. The most central connotation of the word *industrial* is undoubtedly an inclination toward mass production of commodities. The Industrial Revolution in England was essentially a strategy to radically expand the production of textiles for export, originally woolens but increasingly also cotton cloth. This strategy should be understood in relation to both the global historical context and the local ecological conditions in England at the time. English textile manufacturers had been competing for market shares with those of other nations such as the Netherlands. Rather than continue to export raw wool to continental Europe, England in the eighteenth century increasingly turned to manufacturing woolen textiles for export. The rising demand for wool prompted large land owners to expel peasants deriving their subsistence from small-scale agriculture in order to replace them with sheep. The rising numbers of landless people provided a source of (wage) labor for the expanding textile industry. At the same time, the incentive to expand production at lower cost per unit of cloth encouraged technological rationalization, including the large-scale use of water mills. The same incentive stimulated the development of the steam engine, which was the first machine capable of converting fossil fuels (coal) to mechanical energy. Britain's abundant deposits of coal had long been used as a source of heat for both domestic use and manufacturing, in large measure as a less expensive alternative to increasingly depleted sources of firewood, but the Industrial Revolution represented a decisive historical discontinuity largely defined by the adoption of fossil fuels as a source of mechanical energy. The full potential of this new mode of production was realized as British textile manufacturers turned increasingly to cotton fiber from the colonies, which, like the subterranean coal deposits, relaxed the pressure on domestic land. By the end of the nineteenth century, the displacement of Britain's environmental footprint through imports of cotton, sugar, timber, and a number of other products amounted to several times its total land area (Pomeranz, 2000).

The expansion of industrial production in England in the late eighteenth and early nineteenth century was importantly geared to the Atlantic slave trade. First, African slaves provided the bulk of the labor in the colonial plantations that supplied the British cotton textile industry with raw material. Second, the colonial slave owners were major buyers of cotton textiles, as they required inexpensive clothing for their slaves. Third, the cotton textiles from Britain were able to oust the rival Indian textiles that had traditionally been used in trading with slave dealers along the west coast of Africa. Fourthly, the rational organization of production in the colonial plantations served as a model for the design of industrial production processes in England. In other words, the products of the cotton textile industry were used to both purchase and clothe the labor force that provided it with raw material and served as a model for the organization of production. The steam engine, the very rationale of which was founded on the triangular trade between Britain, West Africa, and the American colonies, was the crucial factor in giving Britain the capacity to oust the Indian textile industry on the world market. Later on, it propelled the railways and steamboats with which Britain was able to consolidate its colonial empire. These new modes of rapid and reliable transportation were used not only to move materials, commodities, and labor, but also to deploy troops and apply military coercion in different parts of the world (Headrick, 2010).

Cultural Perspectives on Technology and Economics

Although the incentive to increasingly mechanize production is conventionally elevated to a general principle of technological

progress, it is important to recognize this conception as, to a large extent, a reflection of the historical experience of core sections of the capitalist world system (Adas, 1989; Marsden and Smith, 2005). Technological progress in certain parts of the world frequently hinges on environmental load displacement to other parts, as illustrated by British industrialization in the nineteenth century. Mechanization and industrialization should thus be understood as socioecological strategies rather than mere feats of engineering, particularly since the very feasibility of a given technological system is determined by relative prices of labor and resources in different parts of the world. Although there is a general assumption of continuous evolution, over several millennia, of ever more efficient technologies, the cultural image of technology that organizes conventional historiography reflects a mere three centuries of developments, which are currently being reevaluated in terms of global inequalities and environmental repercussions. To the extent that technological developments in core nations have been based on asymmetric appropriation of embodied labor and land from their peripheries, mainstream visions of 'development' can obviously not be accepted as models for the so-called 'developing nations.' This conclusion is underscored by the apparent, biophysical impossibility of universalizing the patterns of consumption currently enjoyed in 'developed' nations. It has been estimated that if such patterns of consumption were universalized across the globe, the consequent resource demands would require the land surfaces of several additional planets. A similar conclusion is evident from the unlikely prospects of universally implementing industrial technologies in agricultural production. The application of fossil fuel-based technologies to food production has established profitable export industries in several parts of the world, but their dependence on nonrenewable resources, wasteful energy balances, and the degradation of soils and ecosystems precludes their universalization as components of a sustainable development.

The industrial mass production of commodities for export was not an invention of the eighteenth century. There are plenty of historical antecedents going back to the earliest urban civilizations in China, India, and Mesopotamia, but the application of fossil-fuelled steam technology in combination with access to American land and African labor enabled Britain to transcend its own ecological constraints in a self-reinforcing process of capital accumulation that became foundational to industrial society as we know it. The societal transformations generated by these processes were unprecedented, both in the European core nations and in their overseas peripheries. Various attempts to interpret these transformations constitute the bulk of social science over the past two centuries. Fields such as economics, sociology, anthropology, political science, and development studies would be inconceivable without them. To this day, their mainstream understandings of growth, modernity, and development are fundamental to globally shared views of the world.

Economic theory was fundamentally transformed by the historical experience of industrialization (Polanyi, 1944). Prior to the Industrial Revolution, schools of thought such as the Physiocrats perceived agricultural land as the only factor of production capable of yielding a net value. While this economic worldview persists in some parts of the global periphery, industrializing core countries increasingly experienced land as a dispensable asset. Whereas Thomas Malthus worried about how access to land would ultimately constrain economic growth, Adam Smith and David Ricardo argued that, with free trade, labor and capital could compensate for a lack of land. This new economic worldview reflected the experience of Britain in the nineteenth century in two important ways. First, the requirements on land had been disconnected from the need for transport energy, which could now be derived from subterranean deposits of fossil fuels rather than fodder for draft animals. Second, the products of an increasingly mechanized industry could be exchanged on the world market for increasing quantities of land-intensive commodities from abroad. Karl Marx, too, was generally optimistic about the prospects of labor and technology, rejecting Malthus's worries about ecological constraints. In contrast to Smith and Ricardo, however, Marx emphasized that industrial capitalism was founded on accumulation, unequal exchange, and class conflict. These three strains of social thought have continued to provide the basic framework of social philosophy up to the present. Smith's and Ricardo's understanding of the world has largely guided mainstream economics, whereas Marxian and neo-Malthusian (ecological) critiques have continued to challenge it.

Contributions from economic anthropology, such as Stephen Gudeman's (1986), approach economic worldviews as cultural systems that can be analyzed in terms of tacit metaphors and implicit assumptions. From this perspective, the science of economics that emerged in tandem with industrial society can be viewed as this society's dominant mode of self-representation. Its inclination toward formalism and abstraction thus reflects the ambition of nineteenth-century Europe to encompass the cultural diversity of the world it was set to conquer. Its faith in the benevolence of what Smith called the 'invisible hand' of the free market suppressed and replaced concerns about inequality and conflict, such as are expressed in the 'image of limited good' that tends to predominate in peasant societies. This denial of unequal exchange is related to its exclusive concern with monetary exchange values, which ignores the asymmetric flows of materials, energy, embodied land, and embodied labor on which industrial production is ultimately dependent. Marxian analyses of capital accumulation and the neo-Malthusian concerns of ecological economics have revealed how such assumptions of mainstream economic science reproduce a specific worldview that is not only cultural but also clearly ideological.

Of central significance in this worldview is the faith in technological progress. While conventionally perceived as a progressive increase in efficiency propelled by human ingenuity, current concerns about environmental degradation, climate change, and global inequalities raise serious doubts about mainstream cultural conceptions of technology. Rather than a set of purely material engineering strategies for locally solving given tasks, technologies may be viewed as thoroughly social strategies for redistributing time and space in global society (Hornborg, 2011). For a given social category, access to a specific technology may be tantamount to saving time and space, e.g., through increasing speed and a more efficient utilization of land, but citizens of industrial societies tend to be unaware of the extent to which this local saving of time and space would be unthinkable without significant losses

of human time and natural space elsewhere in the world system. The social dimensions of such technological arrangements protrude most clearly when we consider how they are consistently mediated by the market. The rationality of any technology is contingent upon relative prices of labor and resources in different parts of the world. The apparent cornucopia of technological efficiency in certain sectors of the world system is thus continuously subsidized by relatively low-paid labor and resources in other sectors.

To understand industrialism as a specific social form, no less than to understand other types of societies, it is important to conceptualize how cultural and metabolic phenomena interact. Whereas human societies for many thousands of years had been organized around the harvesting of solar energy in the form of food and fodder, the experience of European merchant capitalists in the sixteenth century promoted monetary exchange value as the central incentive of economic life. In other words, money at this time became as widely coveted a vital essence as energy. The difference between money and energy, of course, is that money is ultimately only a cultural concept without any intrinsic metabolic potential. Nevertheless, the accumulation of money in Western Europe prior to the Industrial Revolution was destined to completely reorganize the metabolism of societies throughout the world. Its immediate effects were to set masses of African slaves working on American plantations and landless Europeans toiling in mines and factories, transforming societies and landscapes on both sides of the Atlantic. Its long-term effects are yet to be determined, but contemporary concerns with global inequalities, sustainability, peak oil, and climate change suggest that the future of industrial society poses very significant challenges for humankind.

The interaction of cultural and metabolic phenomena can be illustrated by processes of capital accumulation. In his classical account of industrial capital accumulation in nineteenth-century England, Karl Marx observed that the growth of material infrastructure in the British textile industry was intertwined with the flows of exchange values. The scope for investments in further accumulation of real capital was determined by the success of its owners in amassing monetary profits from selling textiles and other industrial products at prices higher than their costs for wage labor and other inputs. Rather than refer to a labor theory of economic value, it suffices to observe that, for industrial capitalism to be feasible, the price of labor must be less expensive than the price of its products. This observation could be extended to include other inputs such as fuels and raw materials. The central point here, however, is that the accumulation of material infrastructure hinges on social relations of exchange, and that these exchange relations are in turn mediated by cultural conceptions such as 'market price' and 'wage.' This illustrates how cultural concepts can be essential to the formation of physical infrastructure, although our Cartesian inclination to distinguish mind from matter tends to preclude such conclusions. It also enables us to propose a crosscultural definition of capital accumulation because it can be argued that it is a universal feature of productive infrastructures – whether textile factories or agricultural terraces – to intertwine, as requisite to their very existence, cultural concepts and material metabolism. For example, the agricultural terraces of ancient Inca society were built and maintained through ritual exchanges of services mediated by shared conceptions of obligations between the emperor and his subjects. Concepts of 'price' and 'wage,' it can be argued, are no less cultural than these ancient Andean conceptions. In both cases, cultural concepts orchestrate and justify material flows of labor and other forms of energy.

Industrialization and the Sociocultural Condition of Modernity

Industrial society has from the very start implied a radical transformation of human–environmental relations. Urbanization and employment in industry have in various ways detached humans from the ecological systems from which they continue to derive their fundamental metabolic requirements such as food, drink, oxygen, and a comfortable temperature. The modern, urban perception of 'nature' or the 'environment' represents a more abstract and distant view of such material connections than the eco-cosmologies encountered by anthropologists among nonindustrial societies intimately engaged in drawing their sustenance from their immediate surroundings. The physical alienation of humans from natural ecosystems thus generates not only material, ecological problems anticipated in the Marxian identification of a metabolic rift between town and countryside but also a cognitive or cultural incapacity to grasp the connectedness between humans and the remainder of the biosphere. Modern people are generally unable to perceive or estimate the social and ecological consequences of their consumption patterns, which means that the reach of their moral responsibility is much more restricted than their increasingly globalized economic and ecological reach. This predicament was acknowledged already in the Marxian concept of commodity fetishism, but has recently often been referred to as 'consumer blindness.' Such cognitive constraints, of course, aggravate the difficulties of identifying and addressing the mounting, global environmental problems of industrial society. It is, for instance, difficult for individual consumers to sense a connection between their purchases and the abstract threat of climate change.

Sociological theory was born in the nineteenth century as a mode of reflecting on the conspicuous transformations within European society. Large shares of the population shifted from rural community life to a more anonymous, urban existence in the industrial centers and submitted to a rigorous regimentation of everyday work (Frykman and Löfgren, 1987). Social theorists such as Emile Durkheim, Max Weber, Ferdinand Tönnies, and Georg Simmel developed conceptual frameworks for grasping this shift and its many social and existential implications. Karl Marx's concept of alienation was also a contribution to this discourse. In the twentieth century, sociological understandings of the 'modern' condition became increasingly sophisticated. In recent decades, sociologists such as Anthony Giddens (1990) and Zygmunt Bauman (1991) have synthesized the most salient features of this condition. Although it must be remembered that sociological models are ideal types that do not claim to be universally applicable, there are undoubtedly characteristic features of modern life that contrast in significant ways with the kind of life generally experienced in pre- or non-modern contexts. Central aspects of the modern condition include an unprecedented individualism and

reliance on abstract systems of trust such as money and expert knowledge.

The social condition of modernity is generally also reflected in a pervasive worldview, including components such as mind-body and culture-nature dualism, a submission to standardization and discipline (including clocks, work schedules, and calendars), and an orientation toward the future. These cognitive orientations toward dualism, homogenization, and progress have continuously been challenged by dissidents emphasizing the contrary values of monism, diversity, and stasis. Thus, in recent decades, ecofeminists have challenged the Cartesian inclination to objectify nature; postcolonial theorists have challenged the notion that European definitions of order can be universalized; and ecological economists have advocated steady state economics and even degrowth. Such cultural countercurrents are in a sense 'antimodern,' but can be traced historically as pervasive subcultures of modernity from their very beginnings. A matter of contention is the extent to which the Enlightenment should really be viewed as an historical discontinuity. The conventional view is that Enlightenment ideals of rationality and efficiency liberated the potential of modern economics, technology, and politics to disengage from the cultural constraints that had fettered these domains and practices in premodern societies. However, as we have seen, there is currently a good basis for arguing that modern conceptions and practices of economics, technology, and politics remain thoroughly embedded in culture, even if this is not recognized in mainstream ideology.

The extent to which modernization also implies secularization is not self-evident, in part because significant proportions of the population in some modern nations adhere to a religious or at least spiritual worldview, in part because some components of the modern condition (e.g., consumption, or faith in economic and technological progress) arguably have ritual or even religious aspects. This suggests that the so-called Enlightenment did not represent a decisive historical discontinuity in the sense we are accustomed to believing. Beginning with concepts such as 'money fetishism' and 'commodity fetishism' introduced by Karl Marx in the mid-nineteenth century, several critiques of industrial civilization imply that modern phenomena such as economy and technology contain elements that have affinities with the 'magic' that is commonly dismissed as premodern (Taussig, 1980; Graeber, 2011). As Marx realized, the specific cultural idiosyncrasies of industrial capitalism are most clearly revealed through comparison with contrasting cultural conceptions and practices, a method referred to as 'defamiliarization by cross-cultural juxtaposition' (Marcus and Fischer, 1986).

The centrally modern phenomenon of consumption, for instance, can only be understood through cultural analysis (Sahlins, 1976). Jean Baudrillard (1972) and Pierre Bourdieu (1984) have shown that specific patterns of consumption serve to communicate messages about a person's identity. The scope for consumption, viewed as a distinct social activity, has widened with increasing commercialization and affluence, while also serving as a modern source of meanings compensating for a general loss of community, tradition, and existential coherence. In this sense, the driving forces of consumption, and thus also of economic growth, appear to be connected to the existential predicament of individualism and alienation. In preindustrial societies, conspicuous patterns of consumption signaled elite status, whereas in industrial societies the communication of social identity through consumption has been generalized to all classes. Particular types or brands of commodities can thus be broadly associated with particular identities or even occupations. However, the communicative and semiotic dimensions of consumption present a shifting field of meanings, where different social groups continuously attempt to emulate or distinguish themselves from each other. Such cultural processes have been of central significance for patterns of world trade, production, and environmental impacts throughout history, but the affluence and mass consumerism of modern industrial societies have intensified their economic and ecological repercussions (Mintz, 1985).

Development, Underdevelopment, and Sustainability

The expansion of affluent, industrial societies in Europe in the nineteenth century was inextricably intertwined with the social and ecological impoverishment of their extractive peripheries (Wolf, 1982). The development of modern societies and lifestyles in some parts of the world system thus implicated the often detrimental historical trajectories of other parts. Although specific developments in the periphery were frequently induced by interventions from and relations with the core, the resultant differences were generally interpreted as representing separate developmental or evolutionary stages in time. The discipline of anthropology emerged as an auxiliary of colonialism in the late nineteenth century. Its first decades were dominated by an evolutionist outlook that represented industrial civilization as the apex of development, indicating a desirable future for the less advanced nations in the periphery. While much anthropology in the twentieth century has continued to advocate 'development' in former colonies, it is difficult to clearly distinguish the extent to which this ambition remains an heir to Europe's civilizing mission, and the extent to which it represents concern over the detrimental consequences of colonialism (Ferguson, 1999).

The recognition that societies or social systems encompass wider fields of interaction than bounded nation states has been most explicitly articulated in the so-called dependency theory of Andre Gunder Frank (1967) and the world-system analysis of Immanuel Wallerstein (1974–1989). Such global perspectives on national trajectories have been particularly influential in sociology, political science, economic history, and development studies. The common denominator of these perspectives is the recognition that conditions within a given nation are connected in significant ways to its history of exchanges with other nations. Frank and Wallerstein have demonstrated that the economic and technological expansion of early modern Europe was conditioned by global conjunctures, and several scholars have challenged the conventional Eurocentric historiography that accounts for this expansion in terms of uniquely European features of culture, society, or geography. A recurrent explanation of European expansion since the sixteenth century focuses on the unusual alliance between merchant capital and national governments, which provided long-distance traders with military support. The non-Eurocentric historians instead emphasize Europe's position as middleman between New World resources and Old World markets, particularly its ability to use American silver in its

trade with China. As we have seen, the sixteenth-century European conquest of the New World and the subsequent trans-Atlantic slave trade were undoubtedly essential prerequisites of the Industrial Revolution.

The precarious predicaments of industrial society have generated influential political discourses that often serve to avert from the undeniable dilemmas of mounting inequalities, resource depletion, environmental degradation, and climate change. These discourses permeate the research agendas of sciences such as economics, engineering, environmental science, and development studies. One by one, the solutions that have been proposed have generally been dismissed by other researchers as components of the utopian, modernist mythology of industrial society. For example, the faith in a postindustrial dematerialization of the economy has been dismissed as neglecting the extent to which it tends to rely on a displacement of material-intensive industries to other parts of the world system, and the faith in responsible consumerism and recycling has largely dissolved in view of the discouraging records of such policies. Similarly, the faith in substituting for fossil fuels with technologies such as agro-fuels and photovoltaic cells has widely been rejected with reference to the vast land requirements, low energy returns, doubtful environmental benefits, and/or prohibitive costs of these technologies. The recent financial crises of industrial societies in North America and Europe contribute to a widespread anticipation of a major shift in the cultural worldview that has accompanied the global expansion of industrial societies over the past two centuries. A crucial component of such a shift would be to promote policies to distinguish economic globalization from globalization in a purely communicative sense. The continued integration of world society as a network of information flows would not necessarily entail the continued intensification of global flows of matter and energy. To rethink conventional economics, engineering, and political science with this objective in mind is currently a central challenge of industrial society.

Industrialization

Abstract

Sociohistorical investigations of industrialization in the past decade have overthrown inherited models of the uniqueness of early-modern commerce and technology in Europe, path-dependent development, and technological determinism. The global economy has entered a novel stage of institutional experiment and organizational diversity within nation-states.

The past decade has witnessed profound shifts in sociohistorical studies of industrialization. Industrialization is still defined as the process of applying mechanical, chemical, and electrical techniques to reorganize production with inanimate sources of energy. This criterion of industrialization in no way entails a technological determinism. On the contrary, comparative research now accentuates four paradoxes of industrial growth: the composite character of technological practice; the centrality of accidental conjunctures of political and military events; the simultaneous success of institutions that appear to follow incompatible strategies; and delayed positive effects from arrangements that deterred industrialization at earlier historical moments.

The inaugural case of industrialization, usually termed an 'industrial revolution,' occurred in Britain from approximately 1760 to 1860. Britain's coal output rose more than 10-fold in this period, due in part to the installation of steam-driven water pumps in mines. Pig iron production increased more than 16-fold. By far the largest portion of increase in the country's overall productivity came from the textile sector after small innovators such as James Hargreaves and Edmund Cartwright facilitated the mechanization of cotton spinning and weaving in factories. Yet the record is studded with puzzles. In textiles, virtually none of the individuals or firms making initial technological breakthroughs were rewarded via patents or exceptional returns (Clark, 2007). Compared to other times and places, manufacturers in general dedicated little of their profit to new equipment and expansion. Their conservatism is all the more remarkable in view of the uniquely secure demand from colonial markets that British entrepreneurs enjoyed, which lessened the risks of fresh capital investment. It was less the rate of economic growth than its sustained accrual that distinguished Britain from all predecessors. Few investigators maintain that overall global development would look much different today had Britain not led the advance (Horn et al., 2010).

Processes of industrialization across capitalist societies as well as across state-dominated societies with central planning, such as the former Soviet Union, have shared essential similarities. Initially industrialization is marked by massive transfers of labor out of agriculture and into factories that have concentrations of capital equipment. Increases in the productivity of the labor devoted to manufacture come to balance increases in demand for goods, however, and employment in the service sector increases more rapidly than in manufacture after initial industrialization. In the leading industrial societies of Europe, Asia, and North America, employment growth has increasingly concentrated in services, expert professions, and finance. Even in industrialized countries that are net exporters of manufactures, such as Germany, the absolute number of workers in manufacturing has usually declined since the 1970s. Indeed, some national economies, including that of the UK, have become net importers of manufactured goods and net exporters of design know-how and of financial services that put technology to work elsewhere.

Technology as a Composite

Apart from basic principles familiar since Galileo, the machinery of the first industrial revolution emerged independently of scientific discovery. Elites of the European Enlightenment diffused an ethos of invention, but actual technical improvements in Britain drew almost entirely on artisanal experience and its incremental consolidation via the shopfloor and vernacular publications. Technology has continued to operate as a hybrid system of tools combined with responsive know-how, both woven together by broader practices of education and family socialization. Well into the era of mechanized cloth production, one manufacturer in Europe might succeed with a device that proved unworkable for neighbors. Throughout the nineteenth century, centralized facilities with steam power demanded greater hand inputs, including custom equipment and reengineered local installation. Mechanization of simpler processes, such as spinning, incongruously enlarged demand for manual household enterprise that remained resistant to mechanization, such as handweaving.

Britain's jump into steam-powered textile mills appears quixotic in comparative perspective. Already in the seventeenth century, the Chinese had diffused a piston/cylinder steam engine as serviceable as James Watt's. Until Hargreave's spinning jenny and Kay's flying shuttle, Chinese textile equipment developed as dynamically and efficiently as Britain's. Traditions of statecraft led Chinese scholars to disseminate practical manuals on improved farming and technological best practice. The new scholarly consensus is that core regions of China in the late eighteenth century enjoyed mobile and disciplined labor, secure property rights in dense markets, flexible financial instruments, high agrarian productivity, and elastic household formation equal to that of pioneering northwestern Europe. The wider distribution of literacy and of self-motivated

tinkering in Britain probably offers a distinguishing key to its divergent take-off.

Yet explanations of industrialization that highlight the supply of the inputs of labor and technology on one side, as well as wide demand for new consumer goods on the other side, can prove inattentive to what lies between: the social institutions of industrial work itself. What led entrepreneurs to centralize work in mechanized factories? Unlike merchants who gave work out to domestic workers, factory employers could directly accelerate throughput to meet shorter delivery deadlines, increase the obligatory hours of work, regulate and reorganize work procedures to ensure quality or flexibility, and prevent competitors from gaining knowledge of novel improvements in products or technology enclosed behind factory walls. Early industrialization was driven as much by employers' need to steer labor at the point of production as by their need to save on labor as a market input. On the eve of industrialization, the commercial blossoming of domestic putting-out industries across many regions of Europe supported demographic expansion by facilitating early marriage and rapid family formation among younger adults. With galloping rises in population, employers lacked compelling incentives to invest in centralized machine production purely for the sake of economizing on labor.

Indeed, manufacturers and engineers in Britain's initial lead sectors of industrialization rarely justified technological investment by the savings in labor effort. They claimed that such classic inventions as the Crompton spinning mule and the use of chlorine in bleaching works increased turnover and thereby reduced the outlays on supplies and land per unit produced. The management goal, as a textile mill proprietor put it, was to "produce the goods on time." Not unexpectedly, therefore, variation in regional economic variables – such as labor supplies and the level of commercialization of household crafts – correlated very inexactly with variation in the transition to factory systems. Many regions at the forefront of dynamic networks of commerce and putting-out systems by 1750, such as East Anglia, were bypassed in the early Industrial Revolution. These areas show that industrialization did not represent the logical culmination of trade, capital accumulation, separation of labor from independent means of subsistence, and formation of a nonagricultural work force. Entrepreneurial interest in coordinating the production process played a role of its own. When more complex machinery demanded repertoires of skills beyond those of a household shop, factories emerged as centralized knowledge storehouses to communicate informal technical detail to employees while excluding outsiders (Mokyr, 2002).

In today's science-driven chemical, electronic, and biotechnology industries, the composite character of technology in use still guides export economies. Germany, overall the global leader in merchandise exports during the first decade of the current century, maintained its historically intensive apprenticeship systems in middling companies making specialized instruments and capital goods. Even when China recently became the global export leader, shipments of such German machinery continued to widen Germany's trade surplus with China. Social scientists now recognize that China's rapid industrialization stemmed from the late Maoist era of mass education and of state-sponsored rural industry. These earlier undertakings crash-trained a pool of 'mindful hands': adaptable workers who had 'learned by doing' (Bramall, 2007).

Conjunctural Coincidences

Comparative research on industrialization has isolated the massive effects of political and geographical accidents in relation to endogenous commercial evolution. Britain's island focus on naval power combined with the necessity of import substitution during the Napoleonic disruption of Continental markets was crucial for sustaining the country's gradual technological improvements. The vast expansion of material inputs, especially cotton, from North America helped Britain overcome the ecological constraints of its land size. In China, by contrast, promising macroeconomic conditions in the eighteenth century, such as high agrarian productivity and capital stocks, were dissipated due to the Qing empire's experience of overstretch and its lack of incentives to steer ambitious overseas commerce. China's coal reserves in the north were accidentally distant from its most dynamic markets and from southern centers cultivating iron production. More astute imperial settlement and transport policies might have united Chinese mineral deposits with iron making. The more closely social scientists examine proximate conditions, the more they enlarge alternative possibilities for Britain to have fallen into an economic cul-de-sac or for East Asia to have escaped from one two centuries ago (Pomeranz, 2000).

In our day, China's breathtakingly swift rise to manufacturing preeminence also relied on international contingencies. US imports from China increased 10-fold from 1991 until the Great Recession of 2008. Industry-specific studies suggest that Chinese imports account for as much as 40% of a decline in US manufacturing employment in this period. The diversion of US funds to military campaigns after 9/11 and accompanying US divestment from domestic research, education, and infrastructure facilitated a shift of initiative to China.

Conflicts between Diverse Institutional Logics

Karl Marx, perhaps the most famed theorist of industrialization, inferred a single path of factory organization based on cumulative investments in machinery. He expected that advanced firms would mass produce standard wares and simplify work tasks to reduce continually labor inputs per product manufactured. The assembly line made famous by the automaker Henry Ford, as well as the state-run firms of socialist regimes, attempted to embody a similarly rigid logic.

Yet examination of historical diversity has undermined the assumption that industrial development depends on integrating mass production in ever larger facilities. Networks of small enterprises in districts such as Solingen or Neuchâtel in the nineteenth century, and Bologna or Silicon Valley in the 1980s, prospered by creating complementary resources for short runs of custom products, a strategy termed 'flexible specialization.' In place of vertically integrated, hierarchical firms, smaller producers clustered to specialize in discrete stages of shifting production processes or they drew jointly

upon specialized pools of labor and particular supplies for innovative products. The hundreds of modest cutlery firms in the nineteenth-century Solingen, for example, obtained crude blades from mechanical forges and on purchasers' demand custom finished them with steam-powered grindstones into literally thousands of types of cutlery. By 1914, Solingen had outstripped foreign competitors by focusing as much on variety in design as on cost minimization. This alternate course of development appears attractive for manufacturers in mature economies today. Usually with the aid of computers, producers who bear high wage costs may try to compete in the world market by rapidly adapting technology to add value to products through revamped or specialized designs (Sabel and Zeitlin, 1997).

Whether flexible specialization works effectively as an industrial strategy under capitalism depends on political events and on the infrastructure of public institutions, not purely on economic conditions. Firms that remain modest in size seem more adept at adjusting technology to changes in the needs of market niches. Much of the employment growth and dynamism in mature economies is consequently focused in small-scale enterprises. Yet these smaller organizations typically lack sizable pools of funding for research into fundamentally new kinds of technology, and they risk stagnation if they vary products only minutely. For enterprises to share the costs of basic advances in technology, flexible specialization typically calls for a complement of cooperative research centers, universities with ties to business, or other institutes for promoting local technological improvement. The creation of these supporting institutions can grow out of municipal campaigns for local entrepreneurs, out of guild programs for promotion of the trade, and out of scientific provisions by central states. Flexible specialization also requires safeguards against sweatshop wage reductions, so workers have reason to invest in their own skills and to contribute their ingenuity to adapting equipment in changing markets. Labor relations supporting this path of industrialization may emerge unintentionally out of struggle between labor and capital at key political junctures. In the cutlery trade of Solingen, for instance, employers were 'forced into their luck' by powerful unions in the 1870s that successfully pushed for codified procedures to divide productivity gains between workers and employers.

An accelerating need for firms to deploy fundamentally new scientific discoveries has further undermined the accustomed models of factory work. Frederick Winslow Taylor and other 'scientific' managers at the beginning of the twentieth century believed that the division of work into fixed elementary tasks should take primacy. By contrast, corporations embedded in fast-changing scientific communities today find their primary challenge is to respond to novel trends and to speed collective learning of sophisticated skills. The tasks in the nineteenth-century mass production could be carried out separately and their outputs added up to assemble a standard product. Contemporary managers focused on design innovation often find that work processes are more interactive than additive and that the challenge is to encourage mutual adjustments among design and production groups as they address qualitatively new assignments. Firms dependent on continual transformations of knowledge have therefore preferred collegial and participatory work styles over bureaucratic and hierarchical forms.

Intensified global exchange has conversely reinvigorated opportunities for mass production in low-wage regions, because it widened economies of scale for making durable goods parts as well. The consequent outsourcing of simpler manufacturing and services to developing economies has had surprising repercussions. In more mature economies, all but the smallest of companies are negotiating diverse kinds of 'vertical disintegration' (Herrigel, 2010) Two principal causes prevail. The model of high-wage, knowledge-based economies establishing blueprints that are manufactured at arms-length under contract in low-wage offshore regions generally proves infeasible with time. The final products from electronic gadgets to automobiles increasingly take shape as integral wholes. Production groups inform designers of emerging technical blockages and anticipate technological opportunities so that designers incorporate this practical information into a resculpted architecture for products as wholes. With speedups in global competition to innovate, design personnel have to cooperate on the ground with producers and tend to shift location to the offshore sites for more forward-looking integration. Second, products that are engineered for marketing to consumers in developing countries require local reconfiguring expertise. As these two causes ripple together, the developing countries may become better situated than the core countries to cross-fertilize interrelated technologies. The stark divide between developing and developed economies seems to be eroding in favor of islands of advance in each kind of economy. Whether the net effect is enhancement of a developed country's relative ability to add high value to products appears uncertain. Vertical disintegration makes it feasible for new entrants to penetrate quickly the higher-priced segments of an industry (Contractor et al., 2011). Automobile companies that spin off the manufacturing of whole modules become vulnerable to the formidable offshore suppliers of their own creation.

Capitalist firms today encounter an unprecedented flux between competing strategies of manufacture. No single scheme for organizing enterprise can become normative within nations or sectors. Once popular theories about coherent, path-dependent continuity or staged evolution in industrial practice due to national regulatory environments or cultural habit are becoming less credible to social scientists. On the one hand, intensifying global competition may lead even the largest of firms to concentrate narrowly by Adam Smith's model of the division of labor. Companies may strip themselves down to create a single core 'product,' sometimes amounting to only an intermediary assembly or final coordination between components. Digital communication may assist such a contractual parceling of tasks by codifying computerized templates by which product ingredients will be combined (Arrighi, 2007). Computer networks incessantly condense previously untradeable intellectual services into commodity objects. Accordingly, in the 1990s the Boeing corporation undertook to slash expenses by subcontracting not only the manufacture but also the engineering of critical parts for its heralded 787 jetliner. The corporation intended to manage only the overall concept. In the end, however, Boeing with prohibitive delays was left holding dozens of incomplete planes that required expensive fixing prior to sale a decade later. If products are constantly morphing as

integral wholes, firms must safeguard quality by supervising all phases of production and must broaden their palette of activities to cross-fertilize possible contributors to innovation. It looks telling that Boeing recomposed its work in-house by purchasing former suppliers and by retraining the remaining contractors.

Such contradictions within global manufacturing today appear to have made the task of governments that would promote development less calculable. The administrations of Japan, Korea, and Taiwan once were prominent among those that guided local industry into more rewarding stations in the global hierarchy of labor. Such states had the capacity to sponsor industrial leapfrogging in the late twentieth century due to their autonomy from narrowly self-interested business groups and due to their cadres of career servants recruited and remunerated by meritocratic standards. In Japan, the state's amalgam of bureaucratic autonomy and informal social connections to private business managers was key to its stewardship of the domestic computer industry. The central state not only offered tax incentives for domestic computer engineering while discouraging imports, but it also acquired in-depth knowledge of the industrial players to allocate patent information and funds for shrewdly chosen research projects (Evans, 1995). Across historical eras, however, comparative industrial advance cannot be linked to a particular kind of state intervention. Today Japan's ministries of trade and industry help foreign companies set up operations in Japan. Pathways toward technological superiority are increasingly unforeseeable by single governments because progress depends on transnational scientific collaboration.

Positive Legacies of Layered Histories

In the ambiguous and problematic terrains of current economic environments, corporations define their own challenges, and correlatively they experiment outside the institutional architectures of their own nations. Whereas equipment builders in the US traditionally relied on market mechanisms alone to find parts suppliers, today they try out collaboration with state governments and local colleges to assist suppliers at large in labor training and cost reduction (Herrigel, 2010). In these settings of self-reflexive problem solving, the cultural repertoires inherited from largely superceded, residual institutions sometimes function as adaptable resources for coping with uncertainty. Economic historians once assessed as an obstacle to capitalist take-off the historic tendency of extended rural households in China to remain attached to parcels of land rather than to separate completely from the means of subsistence. This Chinese family pattern appeared most particularly to discourage single women from migrating to factories and cities as women did in Western economies. Nowadays researchers suspect that China's lagged maintenance of rural households functions as a cultural reservoir. It sustained traditions of creative and disciplined task rotation as well as of independent household management that have infused factory labor in turn. Large Chinese factories by some accounts operate with thinner managerial staffing than is common in their Western analogs (Arrighi, 2007). Likewise, if only in comparative perspective, investigators suggest that the Maoist legacy of collective provisioning buffers many Chinese industrial workers from the reduction in education and in human welfare that initially accompanied the formation of factory workforces in Europe and North America.

Bedrock Universals

Concentrating workers in factories has everywhere triggered the elaboration of novel ideologies to legitimate the employers' exercise of authority (Bendix, 1974). The mobilization of resources for industrialization also entails new definitions of responsibilities and rights over the factors of production, including guidelines for financing or profit allocation and for protecting workers' health in some measure. State ownership of enterprise alters merely the details of these regulatory problems. In all settings industrialization has called forth new statutory frameworks for governing the flow of labor across nations, cities, and firms. Industrialization leads eventually to procedures for crediting intellectual discovery and for singling creators out for reward, whether in the form of patents and copyrights or through other kinds of recognition. Recognizing acute variations in industrial organization should by no means obscure the overarching epochal transformations.

Abstract

Industrialization includes a rapid transformation in the significance of manufacturing in relation to all other forms of production and work undertaken within national or regional economies. The process is accompanied by technological and organizational change which leads to higher levels of productivity, rising living standards, population growth, urbanization, cultural changes, and shifts in the balance of power among nations. When, how, and why particular societies passed through the process continues to preoccupy social scientists, who for more than two centuries, have elaborated in historical depth and analytical sophistication on 'connections' between techniques of production, transport facilities, financial intermediation, state policies, foreign trade, urbanization, institutions, legal systems, and cultures on the one hand and the observed pace and pattern in different regions of the world economy on the other. Alas these connections cannot be specified, investigated, and weighted in ways that might give rise to a general theory of industrialization for Europe or other continents. There is only the complexity of history.

The Process of Industrialization

Industry is distinct from agriculture, forestry, fishing, mining, quarrying, transportation, finance, trade, and the myriad services that make up the separate but classifiable tasks performed by the workforces of modern economies. Throughout history, men and women manufactured commodities for use or for trade and sale. No society has operated without producing some range and levels of industrial output. Industrialization refers, however, to economic change that is recent and different in scale and scope from the manufacture of artifacts. As a socioeconomic process, industrialization includes a rapid transformation in the significance of manufacturing activity in relation to all other forms of production and work undertaken within national (or local) economies.

Economists, historians, and sociologists have measured and compared industrialization in statistical form as it appeared in national accounts and evolved historically for a large number of countries. Their data shows that as industrialization proceeds, the share of national workforces employed in agriculture and other primary forms of production, as well as the national outputs emanating from them, decline; and the shares of employment and output that are classified as industrial, increase. Output and employment emanating from the third macro-sector of national production, services, goes up or down in relative terms. The term 'services' includes all forms of noncommodity output that are sold (and/or supplied) either to consumers (for instance, health care) or utilized as 'inputs' (e.g., distribution, legal advice, accountancy, etc.) in order to sustain both manufacturing and primary forms of production. Clearly as and when industry grows more rapidly than other forms of commodity output, the allocation of services shifts toward manufacturing and shifts away from farming, fishing, forestry, and mining (Kuznets, 1965).

For sustained development there is no substitute for industrialization, which can be measured as the reallocation of a nation's stock of capital (embodied in the form of buildings, machines, equipment, tools, infrastructure, communications, and distribution networks) away from primary production, toward industrial production. But macro-data is more likely to be available in respect of the foreign trade of nations, which allows observers to measure the progress of industrialization over the long run through the study of predictable shifts in the composition of a country's exports and imports. Sales of domestically produced manufactured exports normally grow in significance; and purchases of foreign manufactures diminishes as a share of total imports (Jones, 1988).

Economic data has been classified in heuristic ways and disaggregated into numerous activities and functions in order to expose the extent, pattern, and pace of industrialization over time, across regions, and among countries. These essentially taxonomic exercises help to define and make concrete a process that has proceeded on a global scale for centuries. They expose national variations from more general or regional patterns and contribute to the understanding of major economic variables that historically have fostered or restrained industrialization in various parts of the world (Kuznets, 1965).

Industrialization has been an important process for the welfare of humankind because the reallocation of labor, capital, and other national resources toward industry has usually been accompanied by technological and organizational change, which led to higher levels of output per person hour; rising living standards; population growth; urbanization; cultural changes; and shifts in the balance of power among nations. Thus, industrialization can also be defined in social, cultural, and political terms, and sociology depicts the history of industrial societies in terms of a set of interconnected characteristics, hegemonic values, and legal systems, represented as functional for the development of modern industry.

How, when, and why particular societies moved from preindustrial to industrial norms, motivations, status, family systems, and modern institutions that characterize industrial society remains difficult to explain. Sociological theories elaborate upon the type of changes required in individual behavior and social institutions for the modern industry to succeed. They contrast 'traditionalistic patterns of action' that are defined as

ascriptive, multidimensional, communitarian, familial, and authoritarian with the types of individualistic, achievement-orientated, mobile, entrepreneurial attitudes and behavior that became dominant in cultures as industrialization took hold. This approach depends upon the vocabularies and concepts drawn from sociology, psychology, and cultural anthropology, and on analyses inspired by Max Weber that continue to be preoccupied with value systems (derived ultimately from religions) that have 'motivated' the 'drive to industrialize' in different national and cultural settings (Parsons, 1971).

Unfortunately, historical records are not clear on whether social changes precede or accompany industrialization. Until the late twentieth century, sociological approaches to industrialization were more concerned with its disruptive, dislocative, and potentially negative consequences for families, communities, villages, and regions, than with its nature, origins, and positive effects on living standards. Read as a social process, industrialization often leads to differentiation flowing from the division of labor, class formation, and uneven regional development. As industry diffuses from country to country, it becomes associated with diminishing returns, deindustrialization, unemployment, and the economic decline of some nations. Pessimistic writings about industrialization are often derived from Marx. Fortunately modern sociological understanding of industrialization combines several traditions and schools of theory with historical enquiry and a more process-centered global perspective, which has exposed how complex, multifaceted, and variable the process of industrialization has become since Marx, Comte, Durkheim, and other canonical social scientists wrote their critiques.

The British Industrial Revolution and the Diffusion of Modern Industry

Modern industry, concentrated in particular regions and towns, housed in factories, organized in corporations and firms, and using machinery and inanimate forms of energy evolved gradually. That evolution has preoccupied generations of economic and social historians who have explained why industry became dominant in some national economies before others and analyzed major forces that carried industrial sectors forward from one stage to another. Their writings are heavily concentrated upon the epoch which opens with the beginnings of the British Industrial Revolution in the mid-eighteenth century and closes with World War I. Latterly, historical literature, dealing with proto-industrialization in Europe and Asia before the First Industrial Revolution and with the delayed industrialization characteristic of Russia, Eastern Europe, East Asia, and Latin America, has emerged. The bibliography of literature on the histories of firms, industries, manufacturing sectors located in villages, towns, regions, countries, and continents, includes entire libraries of monographs, essays, and articles. The volume of research covering millennia of time and every conceivable set of spatial arrangements defies summary. Thus the task for historians (and social scientists) and the aim of this article is to review the theories, patterns, and typologies that have been imposed upon this mass of otherwise incomprehensible local and historical detail (O'Brien, 1998).

Shortly after 1945, when the causes of the wealth of nations emerged to dominate the agenda for the social sciences, historians began to formulate models to make sense of Europe's precocious industrial development. At that time the most accessible heuristic device was to refer 'continental' industrialization to a paradigm case, the British Industrial Revolution, as it supposedly proceeded from the 1750s to the 1840s. On the assumption that Britain's lead could be ascribed to the early diffusion of superior industrial technology, it followed that the economic history of Europe could be understood as the spread of techniques of production and new forms of industrial and commercial organization from the first industrial nation to more backward economies on the mainland. In this perspective, British methods constituted not merely initial practice but best practice with universal application. Diffusion then became a major concept and the central problem for European economic history, at least for the nineteenth century, was to explain Britain's early start and the rate at which other European economies adopted British ways (Landes, 1969).

Yet European statesmen, businessmen, and other contemporary observers rarely perceived of their national goals in terms of a race to catch up with Britain. Indeed many expressed doubts about the 'British way' and historians of European economies have not allowed their accounts of the industrialization of economies on the mainland to be dominated by a model inspired largely by Anglo-American perceptions and experience. Diffusion is now perceived as a complex process of creative adaptation rather than mere emulation. The transfer of technology only succeeds when a matrix of related capacities into which machinery can fit has been built up and is receptive to change (Berg and Bruland, 1998). Once in place, European firms and technologies spawned their own problems, solutions, and national trajectories for future innovation (Mokyr, 1990).

Furthermore, late twentieth-century historical research has restored perceptions of the British Industrial Revolution as a drawn-out process in which the upswings in national income and industrial production of the eighteenth century are no longer represented as 'discontinuities' or 'take offs.' Britain's technological lead has emerged as less novel, more slowly diffused, and eventually successful because it rested upon the evolution of a commercialized economy throughout the British Empire, over several generations before the American and French Revolutions (Crafts, 1985). Comparative historical research which now brings Asian as well as European economies into the frame, has also elaborated upon the foundations of Britain's early start, which were specific to that well-endowed offshore island. For example, the relatively high level of energy consumed per capita and per worker, obviously reflected abundant and accessible supplies of cheap coal (Wrigley, 1988). Located at the hub of a rapidly growing Atlantic economy, when waterborne transport was the cheapest way to conduct commerce, a small island was more likely to reap larger gains from oceanic trade than continental rivals. That locational advantage was, moreover, safeguarded and extended by extraordinarily high levels of public investment in sea power, which over the long run lowered transaction costs for British merchants, provided favored access to colonial and foreign markets, and weakened the economies of Britain's

Iberian, Dutch, and French rivals. Writing long after Trafalgar (where the Royal Navy finally won the centuries-old battle for the Atlantic) and sanctified by an ideology of liberalism, British historians tended to overlook the role of the Royal Navy in securing for British business 'disproportionate' shares of world trade, shipping, shipbuilding, and commercial services (O'Brien and Quinnault, 1993).

Thus the First Industrial Revolution can be represented as something of a special case rather than a paradigm case in the economic history of Europe (Mokyr, 1985).

Regions, Towns, and Proto-Industrialization

Industrialization was a regional process. Modern industry certainly did not spread randomly over national maps but 'clustered' within defined geographical boundaries. Insights are gained by observing the factors and circumstances which prompted industry to locate, grow, and decay in some regions rather than others; and in some places before others (Pollard, 1981). Clearly the geographical matrix for the analysis of economic change must be specified in terms of what the historian is trying to explain; and the rise and decline of regions forms an important component of national economic histories. Where and when markets for commodities and factors of production are bounded in a regional environment rather than in national or multinational spaces, economies constitute the obvious units for study.

Research into European regions of proto-industrialization over three centuries before 1800 promises to create the evidence required for a typology which might help historians explain the long-term evolution of major branches of manufacturing (particularly textiles, but also leather goods, finished metal wares, clocks and watches, and furniture) into mechanized factory industries over the nineteenth and twentieth centuries (Musgrave, 1999). However, no single model has emerged to account for the complex range of cases that historians have uncovered of tendencies for industries to concentrate geographically, to specialize, and to engage in long-distance external and internal trade. Histories of proto-industrialization usually elaborate upon a set of initial conditions which contributed to the availability and willingness of local workers (males, females, and children) to turn from dependence upon agriculture to become involved (either part- or full-time) in manufacturing. These include infertile land, inheritance systems, the sizes of farms, communal rights to land, the cost of alternative supplies of food, the productivity of local agricultures, regional specialization, and competition in the agricultural sector. Populations living close to subsistence levels on relatively small holdings, were affected by the high densities of labor to cultivable land, and they were among the first to embrace the opportunities provided by industrial work to supplement family incomes; and the landless and seasonally underemployed laborers from richer and more commercialized agricultural areas also seized these opportunities.(Kriedte et al., 1981).

But mercantile organization and capital were also required and they usually emanated from towns. Towns housed the majority of educated and innovative people. Productive knowledge was more readily diffused across economies where populations became spatially concentrated into the 'networks' or 'hierarchies' of cities and towns. The development of towns improved the efficiency of labor markets, promoted the commercialization of agriculture, and replaced barter with monetary transactions. Europe's maritime cities established imperial outposts overseas, which fostered international trade and specialization (de Vries, 1984).

By the eighteenth century, the map of industrial Europe could be colored into fairly well-defined regions of proto-industrialization, specializing in the production of textiles, clothing, boots and shoes, clocks and watches, tools, weapons, furniture, household utensils, and pottery. Several of these urbanized regions had survived and adapted to competition over long periods of time. Others had recently emerged as loci of concentrated production. All these industries faced limits to improvements in labor productivity through further refinements to the division of labor or from organizational improvements to the 'putting-out' system.

During the nineteenth century as mechanical innovations came onstream and markets widened through innovations in transport, the long-term development of some regions endowed them with several advantages for transitions to factory systems of production. For example, their sales outlets had been long established; they contained supplies of labor experienced in manufacturing for distance markets; capital and managerial skills were available from urban merchants; and all kinds of other external economies flowed from the prior concentrations of industry in the hinterlands of towns. Local agricultures had long demonstrated their capacity to respond to the demands of industrial populations for food and raw materials (Braudel, 1981–1984).

Yet despite and sometimes because of these favorable historical traditions, many regions of advanced proto-industrialization did not move rapidly forward to embrace new techniques of production and modes of organization. In some cases traditions proved to be more of a hindrance than help, and several regions lacked some essential ingredient for mechanization, such as supplies of cheap energy or engineering skills.

Research into proto-industrialization constitutes a program with explanatory potential, but it only covers certain sectors of modern industry. Producers' goods (iron, steel, ships, transport equipment, bricks, glass, and minerals) as well as some important consumer goods, such as flour, beer, and soap, were not manufactured under conditions that even approximate to a putting-out system. Furthermore, if the research program is to fulfill its promise, we still need to know rather more about the varieties and adaptabilities of organizational forms that are encompassed under the heading of proto-industrialization and also far more about the causes of success and failure, both before, and more importantly, during the transition to the factory system (Cipolla, 1973–1974).

Patterns and Typologies of European Industrialization

Largely because he conceived of European industrialization as a process of diversity rather than uniformity, Gerschenkron produced a heuristic model, which focused research upon variations in the manner in which European economies passed

through the decisive stage of accelerated industrial growth or the 'great spurt.' In his view, Britain forged ahead because the conditions for 'spontaneous industrialization' developed early – and the problem for 'relatively backward economies' on the European mainland was to find effective substitutes for missing (British) prerequisites. Delays exhibited by continental economies in their endeavors to catch up with Britain are imputed to a range of 'prerequisites' for successful industrialization that were available to those who transformed the British economy, but were in shorter supply elsewhere in Europe; and the time that other 'continental' countries took to develop substitutes for their cultural, institutional, and technological deficiencies also added to the delay (Gerschenkron, 1962).

Gerschenkron (like Rostow before him) neglected the concept that natural endowments and the role of the state were factors that affected the British Industrial Revolution, and he concentrated upon other elements of industrialization, which he hypothesized would vary systematically with the timing and degree of backwardness exhibited by 'follower' countries, as they passed through clear discontinuity in the growth rate of industrial production (Rostow, 1965).

Gerschenkron predicted that when historians examined the buildup of modern industry in Europe, country by country, they would observe that the more backward or older the economy was when it began that process, the more rapid would be the rate of acceleration in the growth of industrial production, and the more pronounced would be its reliance on capital as distinct from consumer goods. He anticipated that among 'latecomers,' new industrial enterprises would emerge as being technically sophisticated and capital intensive, larger in scale, and more prone to monopoly. Such enterprises would rely to a great degree upon external sources (banks and the state) for both investible funds and entrepreneurial initiatives. For their markets and supplies of cheap inputs they would depend far less than their British counterparts had upon rising productivity in domestic agricultures. Historical research (inspired by his hypothesis) has not merely widened the sample to include potentially deviant cases from the Austrian Empire, the Balkans, and Scandinavia, but has also deepened the knowledge of British, Dutch, French, Italian, and even Russian industrialization in ways that appear inimical to the survival of Gerschenkron's typology as a usable heuristic device to generalize about European, and Asian, industrialization (Sylla and Toniolo, 1991).

The theoretical and statistical problems involved in delineating phases of trend acceleration seem to be insurmountable and as historians turned away from imperfect and partial indices of industrial and national production to investigate the regional and urban proto-industrial foundations of modern industry, the drama of 'take-offs,' 'spurts,' and 'discontinuities' in macroeconomic history has faded from view.

Expectations that historical records might reveal distinctively national patterns of industrial organization cannot be tested because the data required to quantify and systematically compare the prevalence of larger-scale, more capital intensive, and monopolistic firms across countries cannot be constructed. Furthermore, typologies, which juxtapose continental deviations against the 'stylized' version of British industrialization, now look anachronistic. Late twentieth century research on the British industrial organization reveals variance in scale, capital intensity, and departures from competitive norms across industries throughout the First Industrial Revolution (Floud and McCloskey, 1994). Variations in plant size, competitiveness, and factor intensity are not systematically correlated to backwardness, but are related to legal conditions for incorporation, the development of capital markets, changing technology, and above all to product mix. Long-term changes in the composition of manufacturing output do not expose any systematic or predictable shifts from the production of consumer to capital goods or vice versa (Pollard, 1990).

Nevertheless, transitions from simple to complex processes of manufacturing activity are normally orderly. Thus the initial mechanization and standardization of several consumer-goods industries tended to be located within well-defined regions of specialization, utilizing the investible funds, skilled labor, and entrepreneurial talents available in established proto-industrial regions. Factories emerged on a small scale with relatively low capital–labor ratios to engage in the linear transformation of raw materials into familiar products sold on well-established markets. In many cases resources could be mobilized from within the traditional economy in order to replace imported manufactures or the products of handicraft industry. As manufacturing expanded, as the agricultural sector embarked on mechanization and farmed with chemicals, and as transport networks began to cover national terrains, demand and supply constraints on the expansion of domestic capital goods sectors gradually diminished. At that stage a 'second wave' of industrialization carried economies forward (Mathias and Davis, 1990–1998).

Deviations from a path-dependent process of diversification from simple to complex systems of manufacturing occurred, but these deviations are explicable in terms of country size, natural endowments, comparative advantages within an evolving world economy, direct foreign investment, and state policies. Typologies of European industrialization which pay insufficient attention to geography and foreign trade miss essential elements of the process. Europe developed over the nineteenth and twentieth centuries as a continent of large and small political units, with a skewed distribution of natural resources. As possibilities for foreign trade expanded, different patterns of industrial growth evolved from it, varying from country to country (Aldcroft and Sutcliffe, 1999). For example, at comparable levels of per capita income very few European economies achieved anything like Britain's comparative advantage in the export of manufactures. As late as 1913 the shares of 'manufactured commodities' to total exports varied from under 10% for Greece, Denmark, Norway, and Portugal to over 75% for Britain, Belgium, Switzerland, and Germany, with the rest of Europe somewhere in between. Systematic comparisons of trade data across countries and studies of long-term trends in the composition of net imports (exports minus imports) for major manufactured commodities offers historians prospects for the statistical delineation and comprehension of the patterns of industrialization undertaken by different European economies before and after 1914 (Bairoch, 1976).

General propositions about the role of banks have also proved difficult to force into the format of generalizations. Modern research on financial intermediation has fruitfully shifted attention toward the problem of analyzing responses by banks to industrialization as it proceeded in particular national

and regional contexts. Cameron summarized the results of international comparisons by admitting he lacked criteria to measure their success or efficiency. Although he was prepared to laud the contribution of banks in Scotland and Sweden and to deplore their sparseness in France – an economy which apparently managed to achieve respectable levels of per capita income and industrial output without much help from its banks (Cameron, 1967). For Germany, (once the paradigm example for the positive role of banks) there is now a debated hypothesis that the overpraised Kreditbanken misallocated capital and slowed overall growth (Fremdling and Tilly, 1976). In the Czech Crownlands (Bohemia, Moravia, and Upper Silesia) risk-averse banks did little except supply a modicum of working capital. After 1873 Austrian banks "lost most of their interest in industrial enterprises for years to come." For Hungary it was not the banks but the "unencumbered access to the Austrian capital market" that appears crucial to the beginning of industrialization (Good, 1984). Norwegian commercial banks showed little initiative and failed to play any leading role in the process of economic growth. In general it is difficult to find cases where banks clearly played the progressive and entrepreneurial role in national industrialization (Teichova et al., 1997). In analyzing connections between the state and industrialization Gerschenkron suggested that before 1914 several European governments supplied substitutes for deficiencies in private enterprise, private capital markets, and household demand. Although his observation seems plausible and is based upon historical examples (drawn largely from Russia and Eastern Europe), it has not been possible to subject it to statistical testing because the scale and intensity of governmental intrusion into an otherwise market-led spontaneous process cannot be measured (Gerschenkron, 1962). One macro-economic indicator – the ratio of public consumption to gross national expenditure – shows no tendency to vary in any systematic way across countries (O'Brien, 1994).

Instead economic historians have moved on to classify and to attempt to evaluate potential effects on private industrial investment (domestic and foreign) flowing from the different fiscal, tariff, monetary, and exchange rate policies pursued by European governments over the nineteenth and twentieth centuries; and for this topic there is a bibliography of sophisticated studies which apply macro-economic theory to history (cited in O'Brien, 1994).

Nevertheless to confine investigations into the direct and indirect role of governments to their macro-economic policies would be to neglect the core functions performed by states to promote industrialization, namely the creation and reform of laws and institutions which underpinned the operation and spread of markets for commodities and the factors of production. Such markets operated within a framework of rules, which regulated cooperation and competition among individuals and enterprises engaged in economic activities. One of the central traditions of 'old' economic history was to study the laws, regulations, property rights, and enforcement procedures which molded and constrained economic behavior over those long spans of history before the era of the French Revolution, when 'inefficient' sets of institutions are perceived to have held European economies inside their own concepts of the boundaries of production possibility. That program (associated with the German historical school) has been revived with the aid of theories and a vocabulary borrowed from modern economics (Hoselitz, 1961). Neo-liberal institutional economics has been applied to the history of early modern Europe and suggests that frameworks for the operation of commodity and factor markets emerged in some societies (Holland and England) long before others (Spain and Russia) (North and Thomas, 1973).

Clearly it remains important to understand how governments constrained the progress of industrialization by defining and enforcing inefficient systems of rules and property rights. The general problem resides in comparing legal frameworks for economic competition and cooperation across countries, in analyzing alterations to laws and property rights over time, and in systematically linking specified variations in law to economic growth. Although the research program is concentrated on the early modern period when states established (or failed to establish) conditions for subsequent specialization and the widening of markets in the eighteenth and nineteenth centuries, its relevance to the later era of the 'Second Industrial Revolution' (which witnessed the rise of new industries, such as chemicals, electricity, and motorized transportation, and the concomitant appearance of 'big government' to regulate the operations of corporations, unions, and financial intermediaries) is also clear (Mathias and Pollard, 1989). Historians have work to do and are still some way from theorizing or generalizing about connections between states and industrialization (Tilly, 1990).

Conclusions

A long line of distinguished social scientists and historians (including St. Simon, Schmoller, Weber, Bloch, and Braudel) have offered students of European economic history, theories, concepts, approaches, and typologies designed to help them organize, clarify, and generalize from the vast accumulation of information now in print about the history of European industries. At present when the British Industrial Revolution has reemerged as a special case, the potential for histories of European industrialization constructed around the concept of technological diffusion has been degraded (Landes, 1969).

From philosophers of the Enlightenment, through Marx to the German historical school, scholars of European industrial development have found it difficult to organize their analyses without recourse to stages of growth. Rostow's stage theory certainly provided a memorable vocabulary but his schema is not considered to be a particularly illuminating way to write industrial history (Rostow, 1965). Conceptually, the whole notion of a sharp discontinuity no longer attracts historians of economic growth inclined to analyze that process with biological rather than aeronautical metaphors (like 'take-offs') and to explain accelerations (if, when, and where they might be measured) as the product of fortuitous political events, or basically as the final outcome of a protracted process of institutional change and the prior accumulation of physical and human capital (Braudel, 1981–1984).

Gerschenkron's typology inspired generations of scholars and survives as the best frame of reference for economic historians concerned with placing their research within wider and potentially deeper perspectives that emanate from comparisons across Europe. But more often than not, the

heuristic value of typologies seems to reside in the organization of evidence that simply fails to fit the country or case into a pattern (Sylla and Toniolo, 1991). Meanwhile, and as research upon economies, regions, towns, industries, firms, and factors of production proliferates, no scholar with Gerschenkron's awesome learning and capacity for generalization has emerged to reconstruct an alternative typology which might serve to draw the long history of industrialization into a European frame of reference (Senghaas, 1982).

That is why the majority of economic historians continue to pursue research within the framework of nation-states and to offer their scholarship as a basis for comparative history. Indeed that program is exemplified by most textbooks in the field, which tend to be surveys of foreign scholarship arranged country by country, industry by industry, input by input. Readers of these analytically sophisticated books in economic history are implicitly asked to make intellectual leaps from national histories moving through long centuries of industrialization to comparative history unfolding across Europe. They will certainly find scholarly and detailed elaborations on 'connections' between techniques of production, transport facilities, types of financial intermediation, and state policies, foreign trade, urbanization, institutions, legal systems, and cultures, on the one hand; and the pace and pattern of industrialization, on the other. Alas, their connections can rarely be specified, investigated, and quantified in ways that might suggest how observed variations across regions and countries in the manifold factors promoting or restraining industrialization through time might be 'tested' for significance.

Meanwhile (and after two generations of postwar research on the economic histories of Africa, the Near East, and South East Asia) another meta-narrative concerned with the 'Great Divergence' (or why Europe industrialized ahead of economies located on other continents) is beginning to generate syntheses, generalizations, and exciting controversies for historians to pursue (Landes, 1998; Frank, 1998; Pomeranz, 2000).

This article is a revision of the previous edition article by K. Kraiger, volume 11, pp. 7367–7371, © 2001, Elsevier Ltd.

Abstract

Industrial and organizational (I–O) psychology is the study of the behavior of men and women in work settings. I–O psychologists seek to understand and optimize the effectiveness, health, and well-being both of individuals and of organizations. This article considers the three major areas that comprise the broad domain of the field (personnel psychology, organizational psychology, and human engineering); an overview of the evolution of the field; the scientist–practitioner model and the role of research in guiding science and practice; and finally, factors that are driving demand for research and expertise in I–O psychology.

This article is divided into four main sections. The objective of the first section is to describe the domain of industrial and organizational (I–O) psychology, three major focal areas that comprise it, and to identify typical settings where I–O psychologists work. The second section presents an overview of the evolution of I–O: How the field developed to where it is today. The third section presents the scientist–practitioner model and the role of research in I–O psychological science and in practice. Finally, the fourth section identifies several key factors that are driving the growing demand for research and expertise in I–O psychology.

The Domain of I–O Psychology

Psychology is the scientific study of behavior. I–O psychologists focus on a key aspect behavior, namely, the behavior of men and women in work settings. This brief definition suggests three broad areas that comprise the domain of I–O psychology, the person (i.e., the worker), the work that is performed, and the context in which the work is performed (Zedeck, 2011).

With respect to context, the term 'work setting' may extend far beyond work, and with it, the domain of (I–O) psychology. While most of our lives are spent at work, what happens at work can have a huge impact on people and their families. Likewise, what happens while people are away from work, or in a family setting, can have a significant impact on one's behavior at work. Consider just one example of such 'spillover', the care of children. Research shows that men are taking more overall responsibility for the care of their children (providing one-on-one care, as well as managing childcare arrangements), according to themselves and their wives/partners. This has led to increased work-life conflict, as 59% of fathers in dual-earner couples report experiencing some or a lot of conflict today, up from 35% in 1977 (Aumann and Galinsky, 2009; Halpern and Murphy, 2005).

The influence of personality on the behavior of men and women in work settings is even more significant, because personality is often influenced by events that took place long before an individual began employment. Personality traits relevant to organizations are those psychological characteristics that predict consistent work-related thoughts, motivations, behavior, and other outcomes across situations and over time. Not surprisingly therefore, personality characteristics (e.g., emotional stability, extroversion, conscientiousness, agreeableness, openness) predict important outcomes, such as occupational attainment and advancement, overall managerial effectiveness, the performance of expatriates, learning and skill acquisition during training, counterproductive work behaviors, team cohesion and teamwork, and job and career satisfaction (Oswald and Hough, 2011).

I–O psychologists seek to understand and optimize the effectiveness, health, and well-being, both of individuals and of organizations (Rogelberg, 2007). With respect to individuals, I–O psychology seeks to understand the reasons for behavior, as well as intentions, attitudes, emotions, motives, values, and beliefs in work settings. It also seeks to understand, and to some extent to predict, how people can become effective, satisfied, engaged in their work, committed to it, fulfilled, and rewarded, and how these outcomes can be maintained. With respect to organizations, that is, collections of people working together in a division of labor to achieve a common purpose (Hitt et al., 2011), I–O psychology seeks to understand how they can be sustained and developed. I–O psychology therefore focuses on interactions between people and the settings in which they work in order to gain a deeper understanding of how their behavior can be influenced and enhanced to benefit the individual, the organization, and society as a whole. I–O psychology examines issues at the individual level, at the level of groups or teams, and also at the broader organizational level. It is therefore a multilevel and multiattribute study of behavior (Zedeck, 2011).

Traditionally, I–O psychology has been divided into three major areas: personnel psychology, organizational psychology, and human engineering. The following sections briefly consider each of these. Although we treat them separately, they often overlap considerably.

Personnel Psychology

Personnel psychology is a subfield within I–O psychology. It is an applied discipline that focuses on individual differences in behavior and job performance and on methods of measuring

and predicting such differences. Some of the major areas of interest to personnel psychologists include job analysis and job evaluation; recruitment, screening, and selection; training and development; and performance management.

Job analysis is the study of the work to be done and the personal characteristics necessary to do the work. Job evaluation is the process of rank-ordering jobs in terms of their relative worth to an organization. Recruitment is a set of activities designed to attract talent to an organization. It may be internal to a firm (e.g., across departments or functional areas) or external (e.g., job fairs, university recruiting, company and specialized Web sites, social media). In the hiring process, screening refers to a rough, initial examination (e.g., based on minimum qualifications) designed to identify candidates for further consideration. Selection may involve a variety of methods and instruments, such as interviews, written or performance tests, personality measures, biographical information, reference checks, or background checks. In selecting among applicants for jobs, personnel psychologists are concerned with developing valid and reliable assessment methods that are fair to members of all groups. Their objective is to select applicants who are predicted to perform well on the job. Training and development activities involve learning experiences, planned by the organization, and designed to improve performance at the individual team, or organizational levels. Methods may include, for example, formal classroom instruction, online training, on-the-job training, outdoor training, role-playing exercises, team building, or behavioral simulations. Finally, performance management is a continuous process of identifying, measuring, and developing the performance of individuals and teams, and of aligning performance with the strategic goals of an organization (Cascio and Aguinis, 2011).

Personnel psychology also represents the overlap between psychology and human resource management (HRM). HRM is concerned with the management of staffing, retention, development, adjustment, and change in order to achieve both individual and organizational objectives (Cascio, 2013). As a subfield of HRM, personnel psychology excludes, for example, such topics as labor and compensation law, organization theory, industrial medicine, collective bargaining, and employee benefits. Psychologists have already made substantial contributions to the field of HRM; in fact, most of the empirical knowledge available in such areas as motivation, leadership, staffing, and performance management is due to their work.

Organizational Psychology

Organizational psychology addresses the motivational and emotional side of work. To do that, it typically combines research and ideas from social psychology (the study of power and influence, attitudes and attitude change, communication in groups, and individual and group social behavior) with organizational behavior (a field devoted to understanding, explaining, and ultimately improving the attitudes and behavior of individuals and groups in organizations) (Colquitt et al., 2011).

Organizational psychology typically includes topics such as aging and retirement, turnover, retention, attitudes (e.g., job satisfaction, organizational commitment, employee engagement), fairness, organizational justice, motivation, decision making, stress, leadership, teams, the interaction of work with family (and vice versa), as well as organizational and work design. Managing change is also a key focus within organizational psychology. Such changes may stem from a variety of initiatives, such as mergers and acquisitions, restructuring, downsizing, or various efforts to enhance productivity and quality. For change-management initiatives to be effective, I–O psychologists need to understand thoroughly the theoretical bases for the interventions they use, as well as research to assess the impact of the interventions on people and organizations.

Human Engineering

Human engineering (also known as human factors psychology or engineering psychology) is the study of the capacities and limitations of people with respect to their work environments. The goal is to develop an environment that is compatible with the worker, whether that worker is a pilot interacting with the controls and displays in an airplane cockpit, a computer user navigating a graphical user interface, or a truck driver who uses controls and displays to operate a vehicle.

In a systems approach to human engineering, the human operator is the central figure within a complex sociotechnical system. That system is composed of the operator, the technology (e.g., tools, computers) necessary to complete the required tasks, and the work environment (the organization, physical setting, and task requirements). One approach to system design has been the sociotechnical systems approach, in which design is driven by analysis of the environment, the social system, and the technology system. The objective is to maximize the fit among all three components (Paley and Grier, 2007; Salvendy, 2006).

More recently, human engineering, like much of psychology, has been greatly influenced by advances in cognitive science. To appreciate this, consider two other approaches to system design: user-centered design and participatory ergonomics. With user-centered design, the primary objective is to design systems that explicitly satisfy both the task and information-processing requirements of the human operator. Participatory ergonomics incorporates user involvement throughout the design process, but it goes further, allowing users, with expert support, to complete the design.

Cognitive–perceptual principles guide the design of user interfaces, the primary means by which users interact with systems. As an example, consider the design of a control panel in a power plant. Here are four such principles (Paley and Grier, 2007):

- Logical groupings of displays,
- Consistency of look and function (like items look and function similarly),
- Labels are legible, visible, meaningful, and discriminable, and
- Controls are reachable and movable by the population in the work environment.

Clearly, user-interface designs and system designs can have a major impact on the fit between humans and the environments in which they work.

Having reviewed the broad domain of I–O psychology, it should come as no surprise that I–O psychologists work in a variety of settings (Society for Industrial and Organizational Psychology, Inc., 2014). In academia, they may be full, associate, or assistant professors of psychology, management, organizational behavior, or industrial relations. In other settings they may hold the titles of corporate vice president, director, manager, or staff member of organizational development, management development, human resources research, employee relations, training and development, or leadership development. Finally, they may be presidents, vice presidents, or directors of private research organizations, consulting companies, or other organizations.

A Brief Overview of the Evolution of I–O Psychology

The objective of early industrial psychology was to improve organizational goals (productivity and efficiency), primarily by applying psychology with an emphasis on individual differences through employee selection and training (Koppes, 2007). In 1913, Hugo Munsterberg's book, *Psychology and Industrial Efficiency*, described experiments in selecting streetcar operators, ship's officers, and telephone switchboard operators. His contributions to I–O psychology are noteworthy for his emphasis on the analysis of jobs in terms of (1) the abilities required to do them and (2) the development of testing devices – aptitude as well as work sample tests – that were able to forecast subsequent job performance (Munsterberg, 1913).

Munsterberg's 1917 book, *Business Psychology*, included the results of questionnaires sent to hundreds of laborers. The questionnaires requested anonymous data on attitudes toward their work, involvement in the labor movement, and leisure activities.

Several decades earlier, the scientific management movement began with the goal of bringing order and rationality to the practice of management. Frederick Winslow Taylor was the prophet of scientific management, and the stopwatch was his 'bible' (Bell, 1972). Taylor began his experiments in the steel industry in 1885. His objective was the systematic analysis and breakdown of work into its smallest mechanical elements, and then their rearrangement into the most efficient combination. The objective was to identify the 'one best way' to perform work. In addition to the scientific study of the task itself ('time and motion' study), Taylor argued that individuals selected to do the work should be as perfectly matched physically and mentally to the demands of the job as possible, and that overqualified individuals should be excluded.

Taylor believed that employees should be trained carefully by supervisors (whose own work was also divided into specialties) to ensure that they perform the work exactly as specified by prior scientific analysis. In no case, however, should employees ever be called upon to work at a pace that would be detrimental to their health.

Finally, to provide an incentive for the employee to follow the detailed procedures specified (and closely supervised by line supervisors on the shop floor), Taylor felt that employees should receive an addition of between 30 and 100% of their ordinary wages when the task was done right and within the time limits specified. The first piece-rate incentive system had arrived.

Taylor was interested in the social aspects of work, although he saw little good emerging from the social interaction within work groups. He felt that work groups fostered a level of individual efficiency equal to the level of the least productive worker in the group. In other words, he believed that the efficiency of the group would not be any greater than the efficiency of the least productive member. Thus, Taylor tried to institute a kind of social physics into the workplace.

Both Munsterberg and Taylor were concerned with how workers were selected for jobs, as well as with the individual worker's feelings and aspirations. Although they differed on several issues (notably, on how social structure affected productivity), Munsterberg's writings clearly suggest that he felt that the two emerging fields of personnel selection and social psychology (the study of how people affect and are affected by one another) were complementary (Landy, 1992; Moskowitz, 1977).

When the United States entered World War I in 1917, psychologists Walter Dill Scott, Walter VanDyke Bingham, and Robert Yerkes collaborated in developing intelligence tests that could be used to select and classify recruits. The Army Alpha was administered to individuals with English language skills, while the Army Beta was administered to recruits who were illiterate or did not have strong English language skills. These tests paved the way for large-scale intelligence testing and for later expansion of psychological testing into government, industry, and education (Vinchur and Koppes, 2011).

Other developments at about the same time included the use of rating sheets for interviewers, advances in checking references given by workers, and in statistical methods for estimating validity (the extent to which selection devices accurately forecast job performance). Other kinds of psychological measures also appeared during and after World War I, such as measures of aptitude, interest, and personality. The measurement of attitudes was made possible by the scaling techniques of L.L. Thurstone in 1927, and improved further by Rensis Likert in 1932. Likert-type rating scales (e.g., 'strongly agree, agree, neither agree nor disagree, disagree, strongly disagree') are still popular today.

The Hawthorne Experiments

In Chicago, in 1923, the Hawthorne Works of the Western Electric Company provided the setting for one of the most famous behavioral research efforts of all time. The purpose of the research was to identify variables that affect worker productivity. Experiments by professors Elton Mayo, Fritz Roethlisberger, and T. North Whitehead of Harvard Business School indicated that productivity was directly related to the degree of group teamwork and cooperation. The level of teamwork and cooperation, in turn, seemed to be related to the interest of the supervisor and the researchers in the work group, the lack of coercive approaches to productivity improvement, and the participation afforded the workers in changes affecting them (Pennock, 1930; Roethlisberger and Dickson, 1939). In short, the researchers came to view an organization of workers as a *social system*, in contrast to Taylor's view of an organization as a *technical–economic system*. Interest and research in topics such as leadership, motivation, group processes, and job

satisfaction have direct antecedents in the Hawthorne research (Vinchur and Koppes, 2011).

World War II brought new challenges for I–O psychology, and also many new developments. These included the Army General Classification Test, situational stress tests, and the selection and simulation training of pilots to fly warplanes. In addition, building on work done by German psychologists and that of the War Office Selection Board of the British army in the early 1940s, the US Office of Strategic Services used the assessment center method to select spies and sabotage agents during World War II. Each candidate had to develop a cover story that would hide his identity during the assessment. Testing for the ability to maintain cover was crucial, and ingenious situational tests were designed to seduce candidates into breaking cover (McKinnon, 1975; Office of Strategic Services, 1948).

Post–World War II, the US economy thrived, jobs were plentiful, and developments in I–O psychology focused on job analysis, job evaluation, staffing, training, performance appraisal, labor relations, equipment design, and reducing accidents to enhance safety. The conviction that group behavior and workers' feelings were associated with morale and productivity characterized much of the research and theorizing in what became known as the 'human relations movement' for the next two decades. Influential thinkers such as Douglas McGregor (Theory X and Theory Y managers), Chris Argyris (modern organizations are in conflict with the personalities of mature adults), and Rensis Likert (the 'linking pin' model of integrating small groups into the organization) focused on the fit between organizations and individuals. Their ideas can be summed up concisely: organizations and people need each other, and a good fit between the two benefits both (Shafritz and Ott, 1996).

The 1960s and 1970s

The Vietnam War, baby boomers in the workplace, and the rise of foreign competition led a new generation of employees to question the authority of organizations, which stimulated concerns about democracy, discrimination, and autonomy in the workplace. Major civil rights legislation was passed, including the 1963 Equal Pay Act (outlawing gender-based discrimination in pay); the 1964 Civil Rights Act (Title VII of which prohibited discrimination in employment on the basis of race, color, religion, sex, or national origin); and the Age Discrimination in Employment Act (which forbids discrimination against employees 40 years of age and over). This legislation coupled with major court decisions, such as *Griggs v. Duke Power Company* (1971), significantly influenced research in I–O psychology concerned with job analysis, test validation, and fair employment practices. After publication of the federal *Uniform Guidelines on Employee Selection Procedures* (1978), I–O psychologists became heavily involved in defending (or challenging) tools and techniques used for personnel decisions. Validity generalization (see below) and meta-analysis were introduced as approaches to support generalizing the findings of validity studies across jobs and organizations. At the same time, cognitive-based theories began to emerge in areas such as leadership and motivation. Finally, in 1976 Marvin Dunnete published a one-volume *Handbook of Industrial and Organizational Psychology* to chronicle the evolution, development, and future challenges facing the field.

From the 1980s Forward

With the fall of Communism, the end of the Cold War, and the passage of the North American Free Trade Agreement, a global and diverse workforce began to emerge. Downsizing white-collar workers became more common, along with the widespread restructuring of organizations (also known as process reengineering), and mergers and acquisitions. Passage of the Americans with Disabilities Act (ADA) in 1990 created the need to identify essential job functions, physical requirements of jobs, and brought renewed interest in job design. Likewise, passage of the Civil Rights Act of 1991, which amended the Civil Rights Act of 1964, provided the sanctions for violations of the ADA and outlawed the practice of 'race norming'. Using that procedure, percentile scores on a selection procedure were computed relative to one's own race/ethnic group, and then merged with those from other race/ethnic groups into a single list. The prohibition against race norming subsequently sparked renewed interest in research on fair personnel decisions.

Over the past 30 years, there have been many developments in I–O psychology research and practice. Some of these include, for example, a cognitive perspective on performance appraisals; a shift toward performance management (which incorporates ongoing coaching and feedback); organizational justice theory; the use of personality tests in employment; computerized adaptive testing; and widespread use of the Internet and social media for recruitment, assessment, and selection. Two other noteworthy developments were the Occupational Information Network to replace the former Dictionary of Occupational Titles, the second edition of the four-volume *Handbook of Industrial and Organizational Psychology* in 1991, and, more recently, a three-volume *APA Handbook of Industrial and Organizational Psychology* in 2011.

The Scientist–Practitioner Model and the Role of Research in Guiding Science and Practice

There is a strong connection between research that is conducted using scientific methods and the practice of I–O psychology. For decades, the professional association for I–O psychologists, namely, the Society for Industrial and Organizational Psychology, has endorsed the scientist–practitioner model (Bass, 1974; Cascio and Greene, 2012; Dunnette, 1990; Murphy and Saal, 1990; Rupp and Beal, 2007). That model discourages both practice that has no scientific basis and research that has no clear implications for practice.

I–O psychology is an applied discipline, as reflected in the title of the premier journal in the field, *Journal of Applied Psychology*. At the same time, however, what differentiates I–O psychology from many other applied disciplines is its reliance on scientific methods to produce basic research and theory. That basic research and theory often lead to strategies and systems that are relevant to individuals, teams, organizations, and society. As an example, consider the theory of validity generalization (VG).

A traditional belief among personnel psychologists was that validity coefficients, that is, correlations of scores on preemployment tests with measures of job performance, were highly specific to each employment situation. Hence, an empirical study would be required in each situation, and the ability to generalize validities across similar situations would not be possible.

Schmidt and Hunter (1977) and Hunter and Schmidt (1990) hypothesized that the variability across studies in raw validity coefficients, even when jobs and tests appear to be similar or essentially identical, might be artifactual in nature. In developing a model to test this hypothesis they identified seven potential sources of artifactual, between-study variance in observed validity coefficients, the most important of which is sampling error. Applying a Bayesian statistical model, they demonstrated that when jobs are similar in different employment situations, it is possible to generalize validity to new settings without carrying out an empirical validation study in each new setting.

The more than 500 VG studies and technical refinements of VG procedures that now exist in the literature in applied psychology (for reviews see Murphy, 2003; Schmidt and Hunter, 2003) provide disconfirming evidence that validity is situationally specific, and indicate that VG is a robust phenomenon. Perhaps the most important implication of this work is that it has called attention to the fact that the mean of several validity coefficients may be a better basis for inferring a valid relationship between a predictor (e.g., an employment test) and a criterion (a measure of job performance) than any one coefficient (Society for Industrial and Organizational Psychology, Inc., 2003).

The implications of VG research have direct implications for practice, and several authors have identified key considerations for practitioners to consider when assessing VG evidence (Schmitt, 1996; Wanous et al., 1989). The many studies that VG has enabled have made it possible to develop general principles and theories that have helped to propel the field beyond a mere technology to the status of a science (Guion, 1976).

Some Factors Driving Demand for Research and Expertise in I–O Psychology

Dramatic changes are occurring in the social, legal, political, and economic environments everywhere. Some of these issues include finding and keeping top talent in tight labor markets, and capitalizing on the information revolution in ways that will benefit organizations, such as social media and other Internet-based recruitment sources. Other challenges include managing the performance of geographically dispersed employees and teams (virtual teams), and providing training and development opportunities on demand.

Many of the ways of working that individuals have taken for granted are disappearing – working 9–5, spending an entire career with only one company, or working in an office everyday. Similar changes are happening in organizations. For example, the idea that hierarchy is the best way to manage information flows, that most people will work with team members in the same office, or that the majority of talent will be held within the boundaries of an organization. All of this is shifting, and what is coming in its place is less knowable and less understandable – accelerating developments in technology, accelerating globalization, accelerating demographic changes, and accelerating social trends (Cascio and Aguinis, 2008; Gratton, 2011).

Indeed, this is today's paradigm of work: anytime, anywhere, in real space, or in cyberspace. This presents ongoing challenges in areas such as work-life fit; developing a total rewards package that will attract, retain, and motivate employees at all levels; measuring social networks to identify trusted connections; promoting collective leadership; and promoting and enabling ambidextrous leadership that will identify new growth businesses, while remaining focused on the execution of existing ones (Cascio and Boudreau, 2011). I–O psychology will contribute to the bottom-line success of organizations and to the betterment of employee welfare by developing research-based responses to the workplace challenges wrought by this new paradigm.

Inequality Analysis: Overview

Guillermina Jasso, New York University, New York, NY, USA

Abstract

Inequality is pervasive in the social life, and understanding it is a central task for the social sciences. This article provides an overview of inequality analysis, discussing the framework with its questions and building blocks and surveying the twin branches of theoretical inequality analysis and empirical inequality analysis, the latter only briefly given that dozens of other articles discuss empirical studies of inequality. Substantively, this article identifies two main types of inequality – inequality between persons and inequality between subgroups – and highlights the fundamental questions concerning the determinants and consequences of inequality. Methodologically, it summarizes the major tools for measuring both kinds of inequality, including both scalar measures and whole-distribution approaches. To illustrate theoretical inequality analysis, the article reviews recent examples of a priori explorations, including mechanisms for altering inequality.

Introduction

For all of recorded history, questions about inequality have commanded human attention. From Plato (*c*.428–348/7 BC) and Aristotle (384–322 BC), through John Chrysostom (*c*.350–407) and Gregory the Great (540–604), to Rousseau (1712–78) and Mill (1806–73), and finally to social scientists since the nineteenth century, studying inequality has been central to analyses of the human condition. For example, Plato (*Laws*, Book V) insight that social relations and societies suffer when the largest income exceeds five times the smallest income, John Chrysostom's (Homily 66.3, On the Gospel of Matthew) effort to estimate the proportions poor and rich in the city of Antioch, Jerome's concern that marriage hurts women (and his celebrated advice, "do not marry"), and Gregory the Great's (*Moralia in Job*, xxi) observation, "where there is no sin, there is no inequality," have helped to shape social thought and social science. The measurement tools provided in the twentieth century by Gini (1913–1914), Theil (1967), Atkinson (1970), and others brought new rigor to the study of inequality, laying the foundation for modern inequality analysis.

Framework for Inequality Analysis

At its most general, inequality refers to variability in a characteristic among the units of a group or population. The units may be at any level of analysis, for example, persons, cities, countries. Of course, not all variability rises to the level of inequality, as Aquinas ([1265–1274]1952) argued against Gregory, but certainly variability in social goods does.

There are two main kinds of inequality and two core questions in inequality analysis. The two main kinds of inequality are inequality between units of the population (as in earnings inequality between persons or resource inequality between countries) and inequality between subsets of a population (as in the race earnings gap or the resource gap between subsets of countries). The two core questions address the determinants and consequences of both types of inequality. The starting building blocks pertain to quantitative and qualitative characteristics of the units. For simplicity and clarity, this article is framed in terms of persons but extension to other units (such as cities or countries) is straightforward. Accordingly, we begin with personal quantitative and qualitative characteristics.

Basic Building Blocks

Personal quantitative characteristics are characteristics of which there can be more or less, or on which a person may rank higher or lower. The first kind – of which there can be more or less – is called *cardinal*; examples are wealth, land, head of cattle. The second kind – on which a person may rank higher or lower – is called *ordinal*; examples include beauty, intelligence, athletic skill.

Personal qualitative characteristics are unorderable, categorical personal characteristics. They may be dichotomous – like gender – or polytomous – like race, ethnicity, or religious affiliation. Personal qualitative characteristics give rise to groups and subgroups, with these groups and subgroups defined by the category of a personal qualitative characteristic. For example, the group "residents of the United States" is defined in terms of a category of the personal qualitative characteristic "country of residence," and the subgroups "men" and "women" are defined in terms of the categories of the personal qualitative characteristic "gender."

Both quantitative and qualitative characteristics are at the heart of inequality, and it would be impossible to study either type of inequality without them. The first type of inequality – called *personal inequality* or *overall inequality* – measures inequality in a quantitative characteristic X among a group specified by a qualitative characteristic – for example, income inequality among residents of Illinois or wealth inequality among members of a social club.

Thus, the simple operation of measuring personal inequality – for example, calculating the Gini coefficient or one of the Theil coefficients – requires both a personal quantitative characteristic and a personal qualitative characteristic.

Similarly, the second type of inequality – called *subgroup inequality* – refers to the discrepancy between the distribution (most often the average or other measure of central tendency) of X across two subgroups of a group or population, as in the race wage gap or the gender wage gap, and thus also requires both a personal quantitative characteristic and a personal qualitative characteristic.

The distinction between quantitative and qualitative characteristics, long appreciated in mathematics and statistics (e.g., Allen, 1938:10–11), has since the pioneering work by Blau (1974) come to be seen as structuring behavioral and social phenomena in a fundamental way. Here, we see that quantitative and qualitative characteristics play key and distinctive parts in the study of inequality.

This setup gives rise to a set of basic quantities in the study of inequality. Consider a group or population of size N. Each person has an amount x of the quantitative characteristic X – for simplicity, henceforth income. Arranging everyone in ascending order of their x amount yields the absolute rank i. Three new quantities are immediate: the arithmetic mean μ, the individual's relative rank α (approximated by $[i/(N+1)]$), and the individual's relative income (defined as x divided by the arithmetic mean). These quantities are important both substantively and methodologically. Substantively, both the relative rank and the relative amount are involved in behavioral mechanisms, such as status and fairness. Methodologically, they appear in the formulas for inequality measures and in important tools such as Pen's Parade (1971), which visualizes income as a function of relative rank.

Measures of Inequality

Table 1 presents some convenient formulas for four major measures of overall inequality – the Gini coefficient, one of Atkinson's (1970) measures (defined as 1 minus the ratio of the geometric mean to the arithmetic mean), Theil's (1967: 125–127) mean logarithmic deviation (MLD), and the coefficient of variation (CV) – whose properties are well known (see, e.g., Cowell, 1977; Dagum, 1983; Kleiber and Kotz, 2003). Formulas are provided for both observed and mathematically specified distributions. As shown, the formulas include the quantities introduced above, namely the individual's income amount x, absolute rank i, and relative rank α. As well, the relative amount appears in many inequality formulas (Cowell, 1977; Firebaugh, 1999; Jasso and Kotz, 2008: 71).

Table 1 Some Convenient Formulas for Four Inequality Measures in Observed and Mathematically Specified Distributions

Inequality measure	*Observed distributions*	*Mathematically specified distributions*
Gini coefficient	$\frac{2\sum_{i=1}^{N} i x_i}{\mu N(N-1)} - \frac{N+1}{N-1}$	$1 - \frac{2}{\mu}\int_0^1\int_0^\alpha Q(\alpha)d\alpha\, d\alpha$
Atkinson's measure	$1 - \left(\frac{G}{\mu}\right)$	$1 - \frac{\exp\left\{\int_0^1 \ln[Q(\alpha)]d\alpha\right\}}{\mu}$
Theil's MLD	$\ln\left(\frac{\mu}{G}\right)$	$\ln(\mu) - \int_0^1 \ln[Q(\alpha)]d\alpha$
Pearson's coefficient of variation	$\frac{\sigma}{\mu}$	$\left\{\int_0^1 [Q(\alpha)]^2 d\alpha - \mu^2\right\}^{1/2} \Big/ \mu$

Notes: The letters x, i, and N denote the magnitude of X, the absolute rank (arranged in ascending order), and the population size, respectively. The letters μ, G, and σ denote the arithmetic mean, geometric mean, and standard deviation, respectively. Formulas for mathematically specified distributions are expressed in terms of the quantile function (QF) and the mean μ.
Source: Jasso and Kotz (2008:38).

Probability Distributions

For theoretical inequality analysis, there is no more helpful tool than classical probability distributions. Theoretical analysis using probability distributions begins with selection of a set of modeling distributions for the quantitative characteristic X. A useful set includes distributions with different combinations of lower and upper bounds, such as distributions with and without a safety net and distributions with and without a maximum amount of X. Here, we use three two-parameter continuous distributions whose properties are well known – the lognormal, Pareto, and power-function (Johnson et al., 1994(1995); Kleiber and Kotz, 2003). Together this set includes some desired combinations. The Pareto combines a safety net with no maximum. The lognormal lacks an upper bound, like the Pareto, but, unlike the Pareto, it has no safety net. The power function has a maximum but no safety net. All three are two-parameter distributions and expressed in terms of the mean μ and a second parameter, denoted c, which Jasso and Kotz (2008), building on the literature pioneered by Pareto (1897) and more recent contributions such as Cowell (1977: 95) and Kleiber and Kotz (2003: 78), suggest operates as a general inequality parameter governing all measures of overall inequality – a parameter of which all measures of overall inequality are monotonic functions. In the lognormal, inequality increases as c increases, while in the Pareto and power function, inequality decreases as c increases.

Formulas for the main associated functions of these variates – the probability density function (PDF), the cumulative distribution function (CDF), and the quantile function (QF) – are presented in Table 2. Figure 1 provides visual illustration. Relations among these functions in continuous univariate distributions are well known. The PDF is the first derivative of the CDF, and the CDF and QF are inverses of each other. Visually, the graph of the QF can be glimpsed by turning over the graph of the CDF and rotating it 90°.

For analyzing inequality, the view of choice is the one afforded by the QF (portrayed in the bottom row of Figure 1), which expresses x as a function of the relative rank. And there is no more evocative imagery than that introduced by Jan Pen (1971). Imagine an hour-long parade of all members of society, with each person passing at an equal pace (visible for $1/N$th of the hour) and each person's height proportional to his or her magnitude of the variable. If there is perfect equality, all persons would have the same height, but if there is inequality Pen's Parade would start with dwarfs and end with giants. The QF thus provides a whole-distribution tool for assessing inequality.

Theoretical Inequality Analysis

Some theoretical analyses establish properties of and relations between inequality measures and their decompositions. Others

Table 2 Three continuous univariate distributions and associated functional characteristics

Variate	*Cumulative distribution function*	*Probability density function*	*Quantile function*
Lognormal $x > 0$, $c > 0$	$F_N\left\{\frac{\left[\ln\left(\frac{x}{\mu}\right)+\frac{c^2}{2}\right]}{c}\right\}$	$\frac{1}{xc\sqrt{2\pi}}\exp\left\{-\frac{\left(\frac{c^2}{2}+\ln\frac{x}{\mu}\right)^2}{2c^2}\right\}$	$\mu\exp\left[cQ_N(\alpha)-\frac{c^2}{2}\right]$
Pareto $x > \frac{\mu(c-1)}{c}$, $c > 1$	$1-\left[\frac{\mu(c-1)}{cx}\right]^c$	$\left[\frac{\mu(c-1)}{c}\right]^c cx^{-c-1}$	$\frac{\mu(c-1)}{c(1-\alpha)^{1/c}}$
Power-function $0 < x < \frac{\mu(c+1)}{c}$, $c > 0$	$\left[\frac{xc}{\mu(c+1)}\right]^c$	$\left[\frac{c}{\mu(c+1)}\right]^c cx^{c-1}$	$\frac{\mu(c+1)\alpha^{1/c}}{c}$

Notes: For all variates, $x > 0$; other restrictions as indicated. The expressions $F_N(\cdot)$ and $Q_N(\cdot)$ denote the cumulative distribution function and the quantile function, respectively, of the standard normal variate:

$$F_N(x) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{x} e^{-\frac{t^2}{2}}dt;$$

$$Q_N(\alpha) = \sqrt{2}\,\mathrm{erf}^{-1}(2\alpha - 1)$$

where erf denotes the error function. Inequality is a decreasing function of c for the Pareto and the power-function variates and an increasing function of c for the lognormal distribution.

investigate determinants of inequality, and still others, consequences. This section provides some examples.

Theoretical Inequality Analysis – Properties and Relations of Inequality Measures

Two major sets of properties and relations pertain to (1) operations that increase or decrease inequality, and (2) subgroup structures and decompositions of inequality measures.

Altering Inequality – Transfers. The basic idea underlying transfer operations is that a rank-preserving transfer from a richer to a poorer person reduces inequality, while a rank-preserving transfer from a poorer to a richer person increases inequality (Dagum, 1983). The archetypal case involves transfers from one extreme of the distribution to the other, for example, from the richest person to the poorest person. There is a large literature building on the basic idea, proposing a principle of transfers that measures of inequality should satisfy, together with weak and strong versions of the principle of transfers.

To visualize transfers, Figure 2 presents graphs of the QFs of two members of each of the three variates in Table 2 and Figure 1 – the lognormal, Pareto, and power-function. For simplicity, the distributions are of relative amounts (x/μ), so that their mean is fixed at one. The point where the two curves intersect is the boundary between the set who receive transfers and the set who give transfers. In these two-parameter distributions, the curves intersect only once, and there is a tight link between inequality and transfers. When the leftmost – or poorest – receive transfers, inequality decreases. Thus, the distribution with the less inequality is the distribution whose QF is higher in the left region – the distribution in which the poorest are better-off. For example, in panel C, the Pareto that has the higher minimum income also has the lower inequality (as Rawls (1971) would recognize). Behaviorally, when the income distribution changes from one to another of a within-variate pair, as in Figure 2, and the poorest favor the lower-inequality distribution, it is impossible to know whether they are selfish (maximizing own income) or altruistic (reducing inequality).

But transfers can simultaneously include both rich-to-poor transfers and poor-to-rich transfers. As is well known, when that happens, different inequality measures may yield different orderings. To visualize these situations, Figure 3 reports the QFs of distributions drawn from different variate families. As in Figure 2, the distributions are of relative amounts. In the cases depicted, the two QFs cross twice, so that the economic fate of the poorest and richest is linked, and either both gain or both lose, always opposite to the fate of the middle region. For example, in panel C, the poorest and the richest are better-off in the Pareto than in the power-function distribution, while the middle is better-off in the power-function; similarly, in panel D, the poorest and the richest are better-off in the Pareto than in the lognormal distribution, while the middle is better-off in the lognormal. The pair of distributions in panel D is especially interesting, because the median person is not in the majority – which comprises the poorest 49% and the richest 1.3%.

Subgroups and Decompositions. A large literature examines decompositions of inequality measures as well as subgroup structures. For example, Liao (2006) develops a model-based cluster approach to estimate classes of individuals who share similar levels of income and then extends the Gini coefficient to enable a decomposition into individual inequality and class inequality. In a second example, Jasso and Kotz (2008) show that in a subset of societies, characterized by special income distributions (exemplified by continuous two-parameter distributions or distributions with nonintersecting Lorenz curves), as overall inequality increases, so does subgroup inequality; in such societies, when inequality attacks, it attacks on two fronts.

Theoretical Inequality Analysis – Determinants of Inequality

Wage-Setter Model. Recent work formulates a model in which N wage-setters recommend wages for R workers and each worker's final wage y is a weighted average of the recommended amounts x:

$$Y_r = \sum_{i=1}^{N} x_{ir} w_{ir}$$

where w denotes the wage-setter's weight and the weights sum to one (Jasso, 2009). Thus, the final wage distribution is a linear combination of the recommended wage distributions:

$$Y = w_1 X_1 + w_2 X_2 + \cdots + w_N X_N,$$

where X denotes each wage-setter's recommended wage distribution, Y denotes the final wage distribution, and, as above, w denotes each wage-setter's weight. Fundamental theorems in statistics provide the variance of the final wage distribution:

$$Var(Y) = \sum_{i=1}^{N} w_i^2 [Var(X_i)] + 2 \sum_{i=1}^{N} \sum_{k>i}^{N} w_i w_k Cov(X_i, X_k)$$

Figure 2 Quantile Functions (QFs) of Two Members of Three Variate Families. For simplicity, the distributions are of relative amounts (x/μ). Each plot also includes the graph of the equal distribution, shown as the horizontal line at the value 1. The point where the two members of each family intersect is the boundary between transfer groups.

Figure 3 Quantile Functions (QFs) of Pairs of Distributions Drawn from Different Variate Families. For simplicity, the distributions are of relative amounts (x/μ). Each plot also includes the graph of the equal distribution, shown as the horizontal line at the value 1. The points where the two curves intersect is the boundary between transfer groups. In Panel D, the two curves intersect at α equal approximately 0.49 and 0.987 (the latter not visible in the graph).

Two analytic results follow immediately: First, inequality in the final wage distribution declines as the covariances among the recommended wage distributions go from positive to zero to negative. Second, inequality declines as the number of wage-setters increases.

The two analytic results are particularly easy to appreciate visually in the special case where the recommended wage distributions are identical and equally weighted:

$$\frac{Var(X)}{N} + \frac{2}{N^2} \sum_{i=1}^{N} \sum_{k>i}^{N} Cov(X_i, X_k)$$

In this case, when the recommended wage distributions are perfectly positively associated, the variance of Y reduces to the original variance of X. When they are independent, the covariances are zero and the variance reduces to the original variance divided by N – a steep decline. And when the sum of the covariances is negative, $Var(Y)$ declines still further.

The model can be applied both literally and metaphorically. For example, political parties may be thought of as wage-setters, given that their party platforms operate to produce what may be thought of as recommended wage distributions. Thus, the model implies that the greater the disagreements among parties, the lower the inequality; and the larger the number of parties, the lower the inequality. The model also yields the result that in the special case of two political parties, if their recommended wage distributions satisfy certain conditions (for example, they have equal finite variances and are either independent or identical and perfectly negatively associated), inequality is minimized when the two parties are equally weighted (i.e., share equal support among the electorate).

In both literal and metaphorical applications, the model raises new questions about determination of decision rules (such as number of wage-setters) and diversity of thought (such as how wage-setters come to disagree with each other). More broadly, these results may be part of larger fields. For example, the result on the number of wage-setters may be part of a larger class going back to Condorcet's Jury Theorem; similarly, the result on covariances may contribute to the nascent idea that diversity of thought reduces inequality and that seeking consensus may be counterproductive.

Wage Function with Multiple Criteria. Consider now a model in which each workplace unit has a wage function that it uses to establish the wages for its employees. The wage function may differ across workplace units in the number of employee characteristics it rewards and their weights. For example, some units may reward only a single factor (say, gross sales or output); other units, however, may reward additional factors (say, timeliness or courtesy). In contemporary vocabulary, we might say that the mix of skills and traits rewarded varies across workplace units:

$$Z = \beta_1 Q_1 + \beta_2 Q_2 + \cdots + \beta_K Q_K$$

where Z denotes the outcome (say, ln(wage)), Q denotes the reward-relevant traits and skills, of which there may be up to K, each with an associated coefficient β. Using the same reasoning as in the wage-setter model and the same fundamental results from statistics, the variance of Z is given by:

$$Var(Z) = \sum_{i=1}^{K} \beta_i^2 [Var(Q_i)] + 2 \sum_{i=1}^{K} \sum_{k>i}^{K} \beta_i \beta_k Cov(Q_i, Q_k)$$

Two analytic results are again immediate. First, as the covariances among rewarded skills and traits go from positive to zero to negative, wage inequality in the workplace units declines. Second, as the number of wage-relevant traits and skill increases, inequality decreases. This reasoning underlies a recent application in which the Q characteristics

are specified as relative ranks, so that Z has an exponential distribution in the case of one Q, and becomes Erlang, general Erlang, or mirror-exponential, depending on the number of wage-relevant characteristics Q and their associations (Jasso and Kotz, 2007: 320–321). Substantively, this model has deep sociological roots in the pioneering work of Berger et al. (1966: 44), who argued that status inequality declines when the characteristics generating status are negatively associated.

As in the wage-setter model, this model raises new questions, including questions about the process by which skills and traits come to be independent or dependent and the process by which employers decide which characteristics to reward (and how much). Further, this model points to a new direction in studying the shape of the income distribution, which has long defied easy characterization, namely that it may be a mixture of several orderly distributions specific to particular contexts (such as workplace units, departments of a firm, etc.) and that the key elements may be the number of characteristics valued by employers and the associations among the characteristics.

Assortative Mating. It has been known since Plato (*Laws* V) that positive assortative mating perpetuates social inequality while negative assortative mating reduces it, a powerful insight that informs contemporary social science (Jencks et al., 1972: 74, 211, 233–234, 271–273; Becker, 1991: 228). For example, the variance in the couples' income distribution declines as mating goes from positive assortative to random to negative assortative. What has been less appreciated is that under perfect positive assortative mating, husband and wife are equals, but in the other cases there are varying amounts of marital inequality (Jasso, 2011). Plato (*Laws* VI) quotes the saying, "equality makes friendship," but it was Aristotle (*Nicomachean Ethics*, Book VIII) who would note more trenchantly that love is possible only to equals, thus signaling the price of negative assortative mating. As **Table 3** shows, social inequality and marital inequality are on a collision course. What is good for society is bad for marriage, and what is good for marriage is bad for society.

Table 3 Variance in the married-couple income distribution and in the marital-inequality distribution, under three assortative mating regimes, for the case of identical spousal distributions

X_H and X_W Identical	Association between X_H and X_W		
	Perfect positive	*Independent*	*Perfect negative*
Married couple	$4\mathrm{Var}(X)$	$2\mathrm{Var}(X)$	$[2\mathrm{Var}(X)] \times (1+\rho)$
Marital inequality	0	$2\mathrm{Var}[\ln(X)]$	$\{2\mathrm{Var}[\ln(X)]\} \times (1-\rho)$

Notes: The correlation between the X_H and X_W distributions is denoted by ρ. The correlation ρ is always negative in the perfect negative association case, so that the right-hand factor attenuates the variance in the married-couple distribution and increases it in the marital-inequality distribution. The ordering of the variances across the row is opposite for the two distributions, decreasing in the married-couple distribution and increasing in the marital-inequality distribution, as the association between the two spouses' distributions goes from perfect positive to independent to perfect negative.

Theoretical Inequality Analysis – Consequences of Inequality

Both inequality between persons and inequality between subgroups are pervasive. And it is widely believed that their consequences are equally pervasive. Theoretical inequality analysis provides a disciplined a priori approach, one that yields and makes visible a secret garden of testable inequality effects. The garden, however, requires a key. The key is a theory of some corner of behavior, a theory which turns out to yield inequality effects.

This section summarizes one logically necessary inequality effect and several predicted inequality effects. In every case, the theory has nothing about inequality in its assumptions; yet derivation yields outcomes with inequality in them. And in every case yielding predictions, the predictions are testable and contain no visible terms from the assumptions. In this type of deductive theory, the postulates are "genuine guesses about the structure of the world" (Popper, 1963: 245) and the predictions display the "marvelous deductive unfolding" of the theory (Popper, 1963: 221). The postulates' fruitfulness is evident in the "derivations far afield from its original domain," which "permit an increasingly broad and diversified basis for testing the theory" (Danto, 1967: 299–300). The promise of hypothetico-deductive theory is that a small set of Popperian guesses about deep mechanisms will generate a large and disparate set of effects, including novel predictions, and, conversely, that tests of the predicted effects will help assess the guesses' fidelity to the real world.

The theoretical consequences selected for this summary are derived from a branch of justice theory whose starting assumption is the justice evaluation function. The justice evaluation J represents the assessment that someone (self or other) is justly or unjustly rewarded and if unjustly rewarded whether underrewarded or overrewarded and to what degree. Perfect justice is represented by zero, unjust underreward by negative numbers, and unjust overreward by positive numbers. The justice evaluation function – the Popperian guess – specifies J as a function of the logarithm of the ratio of the actual reward A to the just reward C:

$$J = \theta ln\left(\frac{A}{C}\right)$$

where θ denotes the signature constant, whose sign (called the framing coefficient) is positive for goods and negative for bads and whose absolute value (called the expressiveness coefficient) measures expressiveness (Jasso, 1999: 138). Here interest centers on the experience of (in)justice about income, and thus θ vanishes.

It is important to know the properties of the keys used in theoretical analysis, in order to gauge their appropriateness and their price. Some properties of the justice evaluation function are: First, it provides an exact mapping from the combination of the actual reward and the just reward to the justice evaluation; for example, when A is less than C, J is negative. Second, the justice evaluation it yields is in justice units, not in reward units (as it would be, for example, if the functional form were a simple difference between A and C). Third, it

integrates the two main rival conceptions, the ratio favored by Homans (1961) and others and the difference favored by Berger et al. (1972); this is accomplished via the property of logarithms that the logarithm of a ratio equals the difference between two logarithms. Fourth, it embeds the property that deficiency is felt more keenly than comparable excess (now more commonly known as loss aversion), long considered central to matters of justice (Brown, 1986: 78; Homans, 1961: 75–76; Wagner and Berger, 1985: 719); for example, if the just reward is 10, an actual reward of 5 will have a larger absolute magnitude than an actual reward of 15 (−0.693 vs 0.405). These properties were discussed when the justice evaluation function was introduced (Jasso, 1978: 1401–1403, 1416–1417) and subsequently by Berger (1992: 8) and Wagner and Berger (1985: 719), among others.

Inequality, Poverty, and the Sense of Justice. To begin, that is, before wandering into Danto territory and obtaining predictions from which the justice in the assumptions (via the justice evaluation function) has seemingly vanished, consider a property that is close to the original Popperian guess. Readers who have looked hard at Atkinson's inequality measure in **Table 1** and the justice evaluation function in (7) will not be surprised to learn that the average of the justice evaluations can be expressed as the log of the ratio of the geometric means of the actual rewards A and the just rewards C and thence decomposed into injustice due to inequality and injustice due to poverty:

$$E(J) = ln\left[\frac{E(A)}{E(C)}\right] + ln\left[\frac{1 - I(A)}{1 - I(C)}\right]$$

where E denotes expected value and I denotes Atkinson's inequality (Jasso, 1999: 148–150). Equation 8 also yields further properties; for example, as inequality in the actual rewards increases, the average of the justice evaluations goes deep into underreward territory; and as variability in the just rewards increases, the average of the justice evaluations goes deep into overreward territory (another effect of diversity of thought).

Inequality Effects on Conflict between Subgroups. Consider a group or population in which everyone values income, and the members fall into two subgroups, such as persons from two races or ethnicities or of both genders. In the simplest case, the two subgroups are nonoverlapping on the valued good; for example, the poorest person in the advantaged subgroup is richer than the richest person in the disadvantaged subgroup. The group is characterized by the justice evaluations of its members and each of the two subgroups is characterized by the average of the justice evaluations among its members. Using the Newtonian idea that mass accumulates at a point, conflict between the two subgroups is represented by the absolute difference between the averages of the subgroup-specific justice evaluations. It is then straightforward to analyze the predicted conflict severity (Jasso, 1993).

The theoretical results in the income case indicate that the effect of the proportions in the two subgroups differs across distributional forms for income but that inequality always intensifies the conflict. If income is Pareto, conflict increases as the proportion in the bottom subgroup increases; if income is power-function, conflict decreases as the proportion in the bottom subgroup increases; and if income is lognormal, conflict first decreases, then increases, as the proportion in the bottom subgroup increases, reaching its nadir when the two subgroups are of equal size. As noted, regardless of the variate-specific pattern of the effect of the proportions in the two subgroups on conflict, conflict always increases with income inequality. **Figure 4** provides visualization of these theoretical predictions.

Inequality Effects on the Public Benefit of Religious Institutions. Suppose a subset of the population withdraw from society to

Figure 4 Conflict severity as a function of the proportion in the bottom subgroup, by valued good and cardinal-good's distributional form. In the three cardinal-good societies, the greater the inequality in the good's distribution, the greater the conflict severity (and the higher the vertical placement of the graph). Source: Jasso, Guillermina, 1993. Analyzing conflict severity: predictions of distributive-justice theory for the two-subgroup case. Social Justice Research 6, 372.

a cloister and take a vow of poverty, so that they assume the lowest places in the society's income hierarchy. The benefit to society of the religious institution may be represented by the difference between the precloister average of the justice evaluations and the postcloister average among the noncloistered. The public benefit then depends jointly on the proportion cloistered and income inequality. In every variate investigated, as inequality increases, the public benefit of religious institutions increases. This result suggests that religious institutions are more valuable to the social life when inequality is high, and as well that vocation rates will be higher in high-inequality societies. The model also suggests that the rise of mendicant institutions early in the thirteenth century – the Franciscans and Dominicans – was a response to a switch from valuing ordinal goods, like birth and nobility, to valuing cardinal goods, like money (Jasso, 1999: 165).

Effects of Husbands' and Wives' Wage Inequality on Marital Cohesion. Suppose that marital cohesion depends on the difference between the two spouses' justice evaluations. It is then straightforward to derive several predictions about marital wage dynamics and the further prediction at a higher level of analysis that in societies in which husbands earn more than their wives, marital cohesion increases with husbands' wage inequality and decreases with wives' wage inequality, and conversely (Jasso, 1999: 164). **Table 4** provides a handy visualization of these predicted effects.

Preventing Inequality Effects among a Family's Children. Justice theory not only yields predictions about inequality, it also yields predictions about preventing or mitigating inequality effects. One such prediction states that parents of two or more children who do not all have the same birthday will, to spare them pain, spend more of their toy budget at an annual giftgiving occasion than at the children's birthdays (Jasso, 1999: 164). A further implication is that keeping the sibship in harmony being a universal parental challenge, societies will invent an annual giftgiving occasion. In some societies, it will be New Year's Day, in others the Sixth of January, in still others Christmas or Chanukah or Eid.

Empirical Inequality Analysis

It could be said that the whole of sociology is about inequality. And thus this *Encyclopedia* contains dozens of articles on inequality, most of them empirical. This article will not attempt to summarize them. Instead, we invite readers to read the two other articles that have inequality in their title – Income Inequality; Inequality, Social – and to search for the larger set of articles whose keywords include inequality and the even larger set which in one way or another address inequality matters. Concomitantly, we invite readers to use the tools in this article to classify the inequality matters discussed and perhaps gain deeper understanding. Do the articles treat inequality between persons or inequality between subgroups? Or, at a larger scale, inequality between larger social entities like countries or inequality between subsets of those larger social entities? What are the quantitative characteristics in which inequality is explored or assessed? What are the qualitative characteristics which define the populations and subsets?

As for empirical assessment of the theoretical predictions discussed above, the testing task is in its infancy. But already there are early results. Bellou (2013) reports support for the proposition that as inequality increases in the male wage distribution, the divorce rate declines, consistent with the prediction linking husbands' wage inequality and marital cohesion. Similarly, the recent increase in vocations to the priesthood in the United States is consistent with the predictions on the public benefit of religious institutions. Finally, the perennial surge in US toy sales in the fourth quarter is consistent with the prediction that parents, in order to prevent inequality effects among their children, will spend more of their toy budget at an annual giftgiving occasion rather than at the children's birthdays.

Table 4 Effects on marital cohesion of husbands' and wives' wage inequality

	$X_H > X_W$	$X_W > X_H$
Wives' wage inequality	Increases	Decreases
Husbands' wage inequality	Decreases	Increases

Inequality: Comparative Aspects

Abstract

This article offers a panoramic overview of equality and inequality in human societies throughout history, from an anthropological perspective. Discussing power, status, and economy as major dimensions, it covers a wide range of societal forms, from small-scale groupings of foragers to contemporary large-scale societies, and it also discusses race and caste, colonialism, gender, and age as they have related to social inequality. Types of authority such as big men and chiefs are also noted.

Understanding social inequality requires that it be examined comparatively through time (developmentally) and space (cross-culturally): in prehistoric, historic, and contemporary societies; among those described as 'egalitarian,' kin-ranked, and stratified; with foraging, horticultural, agro-pastoralist, and agro-industrial economies; with diverse types of social and political organization; in all habitable regions of the world; with systems of inequality based on principles of kinship, social roles, sex/gender, age, class, status, power, ethnicity, 'race,' caste, estate, and colonial hegemony.

An analytical framework based on key variables is presented. Because societies continually change, typological pigeonholes and evolutionary 'stages' are avoided, whereas nodes and junctures are identified along many paths, from relatively small, homogeneous, egalitarian societies to large, complex, stratified ones. Recent archeological and ethnographical research on transitions informs this discussion. As the analysis turns to comparison of inequalities among stratified societies, it moves from developmental issues to institutional ones – to the contrasting and interacting principles that underlie such systems and the practices they entail. It concludes with reactions generated among those who experience these systems from above and below, and the role of ideology in their consequences.

Inequality is defined here as sanctioned differential access to valued things, experiences, and conditions in human societies. Comparative aspects are similarities and differences found among systems of inequality as a result of comparing societies in all of their variety: through time (developmentally) and space (cross-culturally), in societies small and large, homogeneous and complex, prehistoric, historical, and contemporary, throughout the world.

Social Inequality

Social inequality has been debated from the times of Aristotle and Plato to those of Rousseau, Karl Marx, Max Weber, and innumerable contemporary authors (Beteille, 1987). The classic triumvirate, 'class' (economic order), 'status' (honor), and 'party' (power) are widely cited as its essential dimensions, with power – the ability to prevail over others – as the virtual independent variable. Powerful people are privileged; powerless people are rarely so, and then only under sponsorship of the powerful. Their perspectives on inequality reflect their places in the system: those who look from below see and experience a different world than those whose gaze and experience it from above, and the latter are the ones in a position to define and explain the system, as well as to enforce it.

This article draws on understandings of social inequality obtained, primarily by anthropologists, through cross-cultural and cross-temporal research focused on peoples who have been otherwise largely ignored: those commonly labeled, if noticed at all, as primitive, aboriginal, tribal, native, indigenous, heathen, nomadic, peasant, untouchable, colonial, minority, ethnic, immigrant, and refugee – in short, those rendered vulnerable for whatever reason, or unreason.

Egalitarian (Unranked) Societies

Dominance and differential evaluation exist in every society, but in some – those often loosely described as 'egalitarian' – they are limited to the elemental roles found in all societies: those of family, sex/gender, age/seniority, specific activities or skills, and cherished or stigmatized personal characteristics. If additional inequalities occur, they are more symbolic than material or political. Inequalities in such societies have received increasing attention from ethnographers and archaeologists in recent years (Flanagan, 1989).

These societies are small, mobile bands of kinsmen, with households as the basic social and economic units. Theirs are subsistence economies derived by foraging wild species, without privileged or curtailed access to resources or the means to obtain them. They share their economic pursuits and rewards without expectation of specific returns in what has been termed 'generalized reciprocity' (Sahlins, 1968). Requisite knowledge and skills are present in every household, extrafamilial authority or occupational roles are rare or absent, and sexual division of labor is complementary, with little or no differential evaluation.

Assertively Egalitarian Societies

Even in 'egalitarian' societies, equality of power, possessions, and prestige is in jeopardy. The Hadza of Tanzania are foragers

[†] Deceased.

who consume the products of a successful foray before embarking on another. Woodburn (1982) describes this as an 'immediate-return system.' He characterizes societies with such economies as being 'assertively egalitarian,' in that their members characteristically resist and sanction attempts to exert authority or to consume resources without sharing.

Relatively Egalitarian Societies

By contrast, foraging economies in which long-term collective investments of resources are employed (e.g., construction and maintenance of corrals for game drives), Woodburn terms 'delayed-return systems': the return on investment of labor is delayed rather than immediate. Although they are egalitarian to an extent found among few non-foragers, and are therefore 'relatively egalitarian,' they entail authority and accumulation untenable in immediate-return societies as a result of the need for coordination of delayed-return activities and preservation of products for use during periods of delay.

All societies whose economies and organization are more complex than those of 'assertively egalitarian' foragers have delayed-return systems. Those with economies and social systems more complex than those of 'relatively egalitarian' foragers are inegalitarian, or 'rank, societies' (Fried, 1967).

Inegalitarian (Rank) Societies

Inegalitarian societies are those wherein members are individually, or more often collectively, hierarchically ordered in their access to valued things, conditions, and experiences. All societies discussed here are, in this sense, inegalitarian. This presentation moves from those of relatively 'small scale' (small in numbers and relatively homogeneous) to those of increasingly 'large scale' (large in population and socially complex). This sequence reflects and extends the strong correlation that exists between scale and inequality.

Affluent Foragers and Farmers: Transition to Assertive Inequality

Some cultural anthropologists and many archaeologists have turned to supplementing largely static extant typologies with analyses of transitions, especially those from unranked to, and within, rank societies (Price and Gebauer, 1995; Kirch and Marshall, 1992).

Rank society emerges when circumstances permit some members to acquire privileged or, in the extreme, exclusive access to essential resources. This has traditionally been attributed to the invention of domestication – primarily of plant species, hence agriculture – and the resulting opportunity for some to control land and command the labor of landless others to till and guard it. Similar conditions obtain for pastoralists' control of their herds.

It has long been recognized that some foraging societies share with early farmers the inequalities characteristic of agricultural and pastoral peoples (Koyama and Thomas, 1981). The most widely cited example is the peoples of the northwestern coast of the United States, who developed maritime economies devoid of domesticated species, combined with a complex and highly inegalitarian social structure (Lightfoot, 1993). This seeming anomaly is explained by the annual runs of salmon which, accompanied by technologies of preservation and storage, provide a food supply as predictable and productive as any domestic crop or herd. Inequality results from the opportunities for some to control the best fishing sites and equipment and to mobilize personnel to exploit them. This system entails ranked kin groups (clans) and their chiefs. The latter accumulate goods provided by their clansmen for subsequent ceremonial, status-enhancing distributions to rival chiefs and clans – the storied potlatch.

Other examples of such systems are found primarily in horticultural societies, which employ two distinct kinds of leadership role and social organization: big man and chief (Sahlins, 1968).

Big Men, Big Women

The simpler of the two structures is the 'big man' (rarely 'big woman') society. The big man's role is an informal, acquired, or achieved status. Through personal charisma and persuasion, he recruits a volunteer following whose number contribute valued goods to a fund that he will ceremonially distribute to a competing big man and his followers (as in a potlatch). Recipients thereby incur a debt to be paid off, and if possible exceeded, in a reciprocal distribution. The magnitude of the distribution is the measure of a big man's stature, while his followers receive credit (and when next he is on the receiving end, goods) proportional to their contributions.

Chiefs

A chief differs from a big man in that his is an office ascribed to him as a result of his paramount position in his clan. Fellow clansmen are his obligatory supporters and he their hereditary headman. As chief, he must behave in a chiefly manner, ever responsible and generous to his clan. His behavior follows from his role; the opposite of the big man, whose role follows from his behavior.

Big man organization may evolve into chieftainship when big men find that kinsmen are more reliable supporters than others and therefore preferentially, and eventually exclusively, recruit them. As kinship becomes the de facto principle of organization, the followers of a charismatic big man may become in effect, and ultimately in fact, clansmen of their paramount kinsman, and he their chief.

Chiefs to Kings, Kinship to Class: Transition to Complex Society

The offices of both chiefs and kings are ascribed on the basis of kinship with their predecessors. But they differ fundamentally: the relevance of kinship for the king stops with his coronation; for the chief, investiture is only the beginning. The king becomes sovereign over all within his domain, beholden to no one; the chief is paramount only among his kinsmen and, as kinsman, is as beholden to them as they are to him. The king rules, accumulates, and consumes; the chief proposes, coordinates, accumulates, and redistributes.

Kingship thus represents the demise of kinship as the basis for social structure, replaced by economic stratification: ownership of productive resources, including land, territory as the dimension of governance, authority and force as its method, and depersonalization as a result of dramatic increases in scale. There appear for the first time, ranked economic classes and cultural categories.

Because reciprocity is the economic hallmark of unranked society, and accumulation for conspicuous redistribution is the hallmark of the big man's and the chief's organization, accumulation for conspicuous consumption is a hallmark of kingship and the state.

Stratification

Contemporary nation states are socio-economically stratified in a variety of complex ways, their populations distributed along continuums of differential access to necessities and rewards. These distributions are often perceived as comprising distinctive, ranked categories – social strata – of people similarly positioned.

An issue to which comparative analysis has made major contributions is the nature and function of stratification: Does it primarily serve to select the best qualified for the most important roles in society by offering them the highest rewards? Or does it serve mainly to withhold opportunities from vulnerable segments of society, thus assuring that there will be people with no choice but to perform cheaply and tractably the necessary tasks shunned by others? Caste in India, and US race/ethnic relations, are examples that support the latter interpretation (Berreman, 1960), as is the status of Nepalese and Brazilian immigrant labor in Japan (Yamanaka, 2000).

Dimensions of Stratification

Power is key to stratification, but class and status are closely linked to it; the three vary together. Stratification systems differ in significant ways, the analysis of which is facilitated by comparison along three axes of inequality. One defines the nature of the ranking, contrasting status strata ('honor and privilege') at one pole and class strata (the 'economic order') at the other. A second axis describes the locus of characteristics that determine an individual's status, contrasting those regarded as intrinsic to individuals (ascribed) with those regarded as extrinsic (acquired or achieved). A third axis addresses the composition of strata: whether they comprise named, organized, acting groups or analytically discernible but unorganized categories. Variations along these axes, together with the cultural explanations that rationalize each system, constitute the significant differences among them.

Acquired Economic Status: Categories as 'Classes,' Groups as 'Sodalities'

Acquired status is based on possessions and privileges, its inequalities defined by economic factors (income, net worth) and their accompanying lifestyles (patterns of consumption, education, occupation). These are classes in which it is useful to contrast: (1) those composing objectively discernible categories, useful to an analytical observer but amorphous, unorganized, and not necessarily recognized even by those who compose them; and (2) those who compose groups that are publicly recognized, members who are aware of their shared situation and its sources, are organized, and are acting in their common interests. Marx recognized this distinction when he described the first as 'groups in themselves' and the second as 'groups for themselves.'

Ranked economic *categories* are here designated simply classes. Ranked, economy-based groups, such as labor unions and professional associations, are designated associations or sodalities.

Feudalism and Estates: Groups with Ascribed Economic Status

Feudal systems are complex agricultural societies comprising hierarchical relations among landed nobility, various levels of commoners, and rural peasants. Because patron–client relationships with respect to land are a defining characteristic, such systems fall well within the 'economic order.' They therefore constitute systems of class stratification (Stavenhagen, 1975). But these are classes with a difference, for they are explicitly ranked, with specified rights and obligations. As long as a person belongs to a given category, he or she shares its rank. However, mechanisms exist – usually economic – by which an individual may, with difficulty, move to another category, thereby acquiring its rank. Status is thus intrinsic to the category but not to the individual. Such named, bounded, and jurally defined categories can be labeled estates so as to distinguish them from classes.

Ascribed Honor: Caste, 'Race,' and Ethnicity

Ascribed statuses of honor are distinguished by the fact that rank is assigned on the basis of membership in differentially privileged and esteemed groups or categories rather than on the basis of activities or possessions. They are also distinguished by the fact that, as a result of ascription, those who share them constitute publicly recognized, self-acknowledged groups. Often they are culturally distinct, cohesive – sometimes corporate – groups *for* themselves. Weber called them status groups. Four types will be contrasted below: 'caste/race,' 'ethnicity,' 'sex/gender,' and age/seniority.

Caste/Race

Status assigned to culturally distinct, socially segregated categories of people on the basis of shared and differentially evaluated characteristics claimed to be innate, is unalterable. 'Race,' as it is socially constructed in the United States, and 'caste' (*jati*), as it is constructed in India, are classic examples. Castes are localized, internally organized, endogamous, and often corporate groups ranked according to conceptions of ritual purity. Most low-ranking castes lay claim to higher status than that accorded them – claims that are routinely ignored or brutally quashed by high castes. Attempts to validate their claims entail status emulation: adoption of high-caste rituals and behaviors, a process familiar in Indian social science and known as *Sanskritization* (Srinivas, 1966). They are successful with exceeding rarity, and then only if backed by unprecedented power.

Stigmatized 'races' in the United States differ from the low castes of India in that they are nationwide social categories rather than localized groups, but they share with low castes their birth-ascribed subjection to disparagement, discrimination, and exploitation, rationalized by accusations of intrinsic worthlessness. Similarly disparaged 'outcaste' groups have included the *Burakumin* of Japan and the *Hutu* of Rwanda and Burundi. All respond to their oppression with resentment and resistance. The only consensus on inequality in these systems is the pragmatic one of who has the power and under what circumstances and with what effects it will be used. When this consensus is breached, the systems are often vigorously challenged. These fundamental similarities are here deemed to be sufficiently significant to justify the combined term 'caste/race,' except where their differences are at issue.

Ethnicity

Ethnicity and *ethnic group* are terms for ascribed identity bestowed on groups or categories that are defined by their distinctive cultural attributes, such as language or religion. They are commonly, but not necessarily, ranked within their societies. If ranked, their status is not wholly ascriptive for, although the ethnic group's ranking is ascribed, the defining attributes of its individual members are acquired through shared socialization – learning – and what is learned can be rejected or forgotten. Therefore, as in the case of estates, rank is intrinsic to the group but extrinsic to individuals, so that individual mobility within the system is possible. If circumstances permit, people can acquire or construct other ethnicities, other statuses (Barth, 1969).

Sex/Gender

Sex is usually a birth-ascribed and immutable category of difference which, in all societies, serves as a basis for division of labor and, in most complex societies, is a basis for inequalities. Gender is the social construction of its nature and significance. Many societies define other genders as well, among them the *berdache*, the 'men–women' of several Native American societies and the 'manly-hearted women' of some of them; Polynesian *fa'a fahini* ('in the manner of women'), and India's 'third sex,' the *hijara*. These, and lesbian, gay, bisexual, and transsexual genders of Euro–US and other complex societies, are but some of the diverse gender roles worldwide. Some are stigmatized, but many are not and occupy conventional or exceptional roles in their societies.

The relative status of the sexes in human societies has been long debated. Universal female subordination is often taken for granted. To challenge this, one has only to look across the full range of human societies, including especially those that resemble the societies in which 99.9% of our ancestors, through time, have lived (Leacock, 1978). Among more complex and inegalitarian societies, one must consider those whose systems of descent, inheritance, and postmarital residence follow the female line. The highest incidence of such systems are found in Southeast Asia and Melanesia, among horticultural peoples in which women own the land, do the lion's share of cultivation of staple crops, and enjoy a high to superior degree of autonomy, authority, and respect.

Gender status correlates positively not only with the prominence of its role in descent, residence, and horticulture, but also with its contribution to the household or kin group economy, whether foraging, horticulture, agriculture, pastoralism, wage labor, or profession. In complex societies, it correlates most highly with the economic contribution made from outside of the household, or 'domestic sphere' (Caulfield, 1981).

In discussing gender inequalities, it must not be overlooked that, although every society has distinctive female and male cultures, the genders are largely socialized in the intimacy of family and kin of both sexes, sharing class, ethnic, caste/race statuses, and environments. They are therefore familiar with one another to an extent that people of other ranked identities are not. However, the extent to which such experiences contribute to respect and empathy cannot be predicted from the fact of contact. As studies of US 'race' relations have demonstrated, contact does not necessarily reduce prejudice and may exacerbate it by seeming to confirm stereotypes, unless it occurs in status-equal circumstances.

US women have long been discriminated against, while sharing class and ethnic status with male family members. In India, women share the ritual and economic status of their male caste fellows, while being subordinated to males. Circumscription of women in activities outside the household is an important symbol of high caste rank. *Sanskritization*, caste-status striving, entails increasing subordination of women (Berreman, 1993).

Age/Seniority

Age categories and cultures, like those of gender, are ascribed, socially constructed, familiar to all, and highly variable. As a basis for inequality, age and seniority are at their minimum in unranked societies. Societies organized in lineal kin groups or clans commonly place great importance on seniority, and the first born in a senior (most often male) lineage becomes the paramount.

A number of societies, the most thoroughly reported of which are East African cattle herders, are organized into ranked, age-based groups, more often male than female, whose members share distinctive ritual, economic, military, or other privileges and responsibilities.

Comparative studies of age in other kinds of societies include Mead's classic *Coming of Age in Samoa* (1928), which challenged the universality of adolescence as a period of trauma, and Henry's *Personality and Aging* (1973), which argued that individuals are regarded as persons to the degree that they possess symbols of attachment to their social system, and that in the United States such symbols (gainful employment, license to drive) are often withdrawn from the elderly, leading to the experience of diminished personhood and resulting in social suffering, hostility, and depression. This is precisely the kind and consequence of denial of full humanity inflicted by racism, casteism, ethnic, and gender discrimination.

Colonialism: International Hegemony

Relationships between colonizer and colonized are among the most powerful of the world's structures of domination and exploitation (Asad, 1973). In its classic context, colonialism

has referred to nations and peoples annexed for their natural, manufactured, or human resources by one of the 'great', usually European, maritime powers. Subsequently, the concept has been directed to other contexts, as in 'third-world colonialism' (hegemony over developing nations, often by their erstwhile colonizers), and 'internal colonialism' (domination of minorities within developed nations, e.g., African Americans, Palestinians in Israel).

By analogy, 'academic colonialism' refers to the dominant role well-funded researchers from 'advanced' nations play in 'developing' nations, while local scholars are scantily funded, if at all. It is most damaging and resented when indigenous scholars are evaluated by the standards and fashions of colonial countries, ratified by foreign degrees, and by publication in foreign journals, in colonial languages. Social and behavioral scientists, perhaps more often than others, may find themselves strangers in their own academies and virtual pariahs in world scholarship (Saberwal et al., 1967).

Full Circle: Modern Egalitarian Societies?

Egalitarian social systems require egalitarian economies. Both have been on the agenda of utopian communities and ideal societies studied by social and behavioral scientists: Soviet and Chinese communes, Israeli kibbutzim, socialist societies, and anarchist communities (Barclay, 1982), as well as the American countercultural communities of the 1960s–70s and various egalitarian cults. Many live in small, self-contained communities, combining interdependence and individual/familial autonomy bound by ties of kinship (usually fictive) and sharing ideology and communal activities, while avoiding insofar as possible, participation in the complex society, economy, and politics of the world system. They often pursue subsistence economies through cooperation, sharing, and reciprocity; their production is for use rather than profit; they abjure private property, accumulation of wealth, hierarchies of authority or privilege, and status symbols. That is, they reproduce the social and economic practices of the small-scale, 'assertively' or 'relatively' egalitarian societies with which human societies began and for so very long survived. Prehistoric, recent, and current exemplars have virtually all succumbed to the appetites, blandishments, and requirements of stratified, state-organized producer–consumer society.

Bodley closed *Victims of Progress* (1975) with the observation that small-scale, egalitarian culture 'is gone – after a very long and successful tenure,' and it seems that the presently dominant, stratified "culture of consumption … too, will disappear … but after a very brief and preposterous career."

In the early twenty-first century, that remains to be seen. Recent times have seen a decline in a number of the varieties of human inequality discussed here. Colonialism of the conventional historical–political type is mostly gone (although it may remain in other forms); as a matter of human rights, the tendency in much of the world has been to try to abolish at least official discrimination on the basis of race, ethnicity, gender, and age. With increasing global interconnectedness, on the other hand, large-scale transnational migration and refugee streams from crisis regions have led to the formation of large vulnerable populations whose links to states, markets, and local communities are extremely tenuous. At the same time, dominant market conditions have tended to increase class inequality in much of the world, including North America and Europe. These conditions appear to be volatile, however, and it is not obvious that contemporary modes or degrees of inequality will be permanent.

Inequality Measurement

Abstract

This article reviews the core issues of inequality measurement and explains the relationship between underlying theoretical concepts and practical judgments. The main tools of distributional analysis are used to show the social welfare underpinnings of standard ranking principles and to derive families of inequality indices. Developments that focus on income differences and reference income levels are also examined.

Introduction

Inequality measurement is principally concerned with the comparison of statistical distributions of a specific economic or social indicator. The comparisons usually, but not necessarily, involve distributions among persons or households and involve quantitative methods. The motivation for considering inequality measurement in this way is both analytical and practical: the principal concepts reviewed in this article are of concern to theoretical and applied economists, to other social scientists and also to policy analysts. The subject touches on questions in several disciplines other than economics.

Inequality measurement in its modern form derives some of its intellectual heritage from statistics and is considered by some to be a branch of welfare economics. The subject is related to, but distinct from, the measurement of concentration, poverty, or relative deprivation. Inequality measurement in economics is perhaps most often applied to the study of income distributions but is also used in connection with the study of wealth, expenditure, and other indicators of well-being.

To introduce some of the main issues consider the example in Tables 1 and 2, taken from an easily accessible source and giving a convenient snapshot of what happened to the distribution of income in the United States over 40 years. From Table 1 it is clear that the bottom decile of the income distribution experienced a 12.8% growth over the period (in real terms) while the top decile grew by almost four times as much (48.7%). Table 2 describes what happened to the average incomes of particular *groups*. The average income of households in the bottom fifth of the distribution grew by just 8.5% over the 40 years while the average income of households in the top fifth grew by almost 60%. We return to the use of the concepts of quantiles and shares after introducing some of the technical equipment needed for analyzing income distributions.

This brief discussion suggests a substantial increase in inequality in the United States in the late twentieth century and early twenty-first centuries. But by how much did inequality increase? Can the intuitive method of inequality comparisons suggested in the example be made precise and interpreted within the context of standard economic analysis? The purpose of this article is to provide a succinct overview of the role played by economic theory and other abstract principles in this class of problem and how to make precise and to interpret inequality comparisons such as those suggested in the example.

Tables 1 and 2 also illustrate some of the practical issues that have to be resolved when implementing the principles of

Table 1 Quantile incomes and growth, United States 1971–2011

	q-*Quantile*		
q	*1971*	*2011*	*Growth*
10%	$10 637	$12 000	12.8%
20%	$18 818	$20 262	7.7%
50%	$44 707	$50 054	12.0%
80%	$75 271	$101 582	35.0%
90%	$96 564	$143 611	48.7%
95%	$119 532	$186 000	55.6%

Note: Columns two and three give the upper limit of the bottom 10%, 20%, … of the population. Incomes are in 2011 dollars; the income-receiving unit is the household.

inequality measurement: Should the focus of analysis be on families, households, or individuals? How the income defined and what problems may the definition of income present for formal inequality analysis?

We deal first with the principles underlying these basic issues (Section Basics) and then we examine three theoretical approaches to the problem of inequality measurement (Sections Social Welfare and Inequality and Income Differences).

Basics

Components of the Problem

The framework adopted here is not the most general approach, but one that is suitable for setting out the key ideas. We begin by considering the basic building blocks and then show how to assemble the constituent parts.

Income and Income Distribution

At the center of the problem there is some entity, which we will call 'income,' but which in practice could be wealth, expenditure, or some other economic quantity, the distribution of which is of particular interest. It is important that this be cardinal (like height or weight) otherwise many of the concepts used below will not be well defined. There are cases where one wants to discuss inequality among distributions over ordinal variables such as self-reported health but these raise special problems, which are not discussed here – see Allison and Foster (2004).

Income is distributed among a number of income receivers, which we will refer to as 'persons,' although the income receiver in practice may be a family or household (we return to households below). Suppose that there is a known number of income receivers n and that person i has income x_i. The *income distribution* is then simply the vector

$$\mathbf{x} = (x_1, x_2, \ldots, x_n) \qquad [1]$$

The set of all possible income distributions X is a subset of n-dimensional real space. The nature of X is going to depend in practice upon the precise definition of 'income': is it logically possible to have a zero value of x_i, for example? Or a negative value? As a working assumption we will take it that X consists of all vectors (eqn [1]) such that $x_i \geq \underline{x}$ and leave open the specification of the lower bound $\underline{x}$ for particular instances of the inequality-measurement problem. Representations of the income distribution other than eqn [1] will appear later in the article.

Indices

The topic of inequality measurement suggests that there ought to be an inequality measure (or measures). A natural interpretation of an 'inequality measure' is as an index I that, given a particular income distribution $\mathbf{x}$, yields a number that is taken to be the amount of inequality exhibited by the distribution. In some respects, the index I behaves like other well-known summary statistics of distributions, such as the mean

$$\mu(\mathbf{x}) := \frac{1}{n}\sum_{i=1}^{n} x_i \qquad [2]$$

and the variance

$$\mathrm{var}(\mathbf{x}) := \frac{1}{n}\sum_{i=1}^{n} [x_i - \mu(\mathbf{x})]^2 \qquad [3]$$

In fact a simple transformation of the variance can be used as an inequality index, known as the *coefficient of variation*:

$$I_{\mathrm{CV}}(\mathbf{x}) := \frac{\sqrt{\mathrm{var}(\mathbf{x})}}{\mu(\mathbf{x})} \qquad [4]$$

One of the most commonly used indices in practice is the *Gini coefficient* defined as

$$I_{\mathrm{Gini}}(\mathbf{x}) := \frac{1}{2n^2\mu(\mathbf{x})}\sum_{i=1}^{n}\sum_{j=1}^{n}|x_i - x_j| \qquad [5]$$

This has the natural interpretation of a normalized average of the average income differences between pairs of people in the population. The inequality measures eqns [2] and [5] have the advantage that they can be used also in cases where 'income' is negative (a situation that can often arise when analyzing wealth distributions).

There are many more inequality indices in common use, but rather than running through an exhaustive list, it is more useful to examine the principles that have usually been applied to construct indices. We do by considering a priori what constitutes a 'suitable' inequality measure, the issue addressed in Section Axioms.

Ranking and Dominance

An apparently more flexible interpretation of the idea of inequality measurement is the idea of an inequality *ranking*. This is a partial ordering that picks up the general flavor of the kind of comparisons that we suggested in the introduction; the partial ordering is typically captured by a simple representational tool. Consider three of these, each of which is defined for negative as well as positive values of income.

The first of these tools is *Pen's parade*, named after the famous parable introduced by Pen (1974, ch. 3), which is simply the inverse of the empirical distribution function. To depict it, let $x_{[i]}$ denote the ith smallest component in the vector eqn [1] – the ith smallest income. Then take the collection of points

$$\left(\frac{i}{n}, x_{[i]}\right), \quad i = 1, 2, \ldots, n \qquad [6]$$

From this simple definition, we can also introduce the idea of *dominance*. Take two distributions $\mathbf{x}'$ and $\mathbf{x}''$ in X, where $\mathbf{x}' = (x'_1, x'_2, \ldots, x'_n)$ and $\mathbf{x}'' = (x''_1, x''_2, \ldots, x''_n)$. If it is true that $x'_i > x''_i$ for all $i = 1, 2, \ldots, n$ then we say that $\mathbf{x}'$ strictly Parade-dominates $\mathbf{x}''$.

The resulting graph plots income quantiles against population proportions: $x_{[i]}$ is the quantile corresponding to the bottom q percent of the population where $q = 100\frac{i}{n}$. To illustrate the concept, we use the information in Table 1 to produce a graph that looks like Figure 1. In Pen's parable, we imagine the whole population (seen as individuals rather than households) arranged in order on the (0, 1) interval where each person's height has been altered in proportion to his/her income; the average-height income recipient in 1971 is located at position 0.58 in Figure 1 (in other words, at a point 58%

Figure 1 Parade diagram corresponding to **Table 1**.

along the horizontal axis the height of the Parade is exactly mean income), but in 2011 the average-height income recipient is located at position 0.61. Although the distribution of 2011 Parade-dominates the distribution in 1971, it is clear from Table 1 that overall the Parade shifted upward in an uneven fashion over the 40 years with the incomes of the very rich (95% quantile) growing more than four times faster than those of the poor (10% quantile); this shift suggests increased inequality over the period. However, by itself the Parade does not tell us much about inequality directly, although concepts closely related to it are widely used to characterize inequality comparisons. It is common to use *quantile ratios* for distributional comparisons; for example, the popular '90–10 ratio' is given by $x_{[k]}/x_{[j]}$, where j and k are, respectively, the smallest integers satisfying $j/n \geq 10\%$ and $k/n \geq 90\%$. In the example above, this ratio increased from 9.08 to 11.97. Furthermore, there is an important interpretation of the Parade that will be discussed in Section Ranking Distributions below.

For the second and third concepts, we use the $x_{[i]}$ to derive the normalized income cumulations; for any, $i = 1, 2, \ldots, a$ these are

$$c_i := \frac{1}{n}\sum_{j=1}^{i} x_{[j]} \qquad [7]$$

Then the *generalized Lorenz curve* (GLC) is given by the graph of

$$\left(\frac{i}{n}, c_i\right), \; i = 1, 2, \ldots, n \qquad [8]$$

Again we have a natural definition of dominance: for two distributions $\mathbf{x}'$ and $\mathbf{x}''$ in X if it is true that $c_i' > c_i''$ for all $i = 1, 2, \ldots, n$ then we say that $\mathbf{x}'$ strictly GLC-dominates $\mathbf{x}''$. For the example we used earlier, the GLC is illustrated in Figure 2, derived from Table 2. The definitions of Parade- and GLC-dominance can be extended to cases where the two distributions do not have the same number of incomes – this step makes use of the 'population principle' defined in Section Axioms.

The GLC plots the normalized income of the bottom $100q$ percent of the population against q and, although the 2011 distribution GLC-dominates 1971, it is clear that over the period the growth of these group averages was not evenly distributed – the higher was q, the higher was the growth over 1971–2011. (This is easily inferred from Table 2: for example, the average income of the top 20% grew almost seven times as fast as the average income of the bottom 20%.) Once again, although the GLC does not give information about inequality comparisons directly, there is an important welfare-economic interpretation (in Section Ranking Distributions). In addition, a small modification of the GLC yields one of the central concepts of distributional analysis. Dividing c_i in eqn [7] by the mean $\mu(\mathbf{x})$ gives the income share of the bottom $100\frac{i}{n}$ percent of the population. The graph of the (population–proportion, income–share) pairs

$$\left(\frac{i}{n}, \frac{c_i}{\mu(\mathbf{x})}\right), \; i = 1, 2, \ldots, n \qquad [9]$$

gives the *Lorenz curve*. Also, for two distributions $\mathbf{x}'$ and $\mathbf{x}''$, if it is true that $c_i'/\mu(\mathbf{x}') > c_i''/\mu(\mathbf{x}'')$ for all $i = 1, 2, \ldots, n-1$, then we say that $\mathbf{x}'$ strictly Lorenz-dominates $\mathbf{x}''$. In the case of the example using US data this is illustrated in Figure 3: the Lorenz curve plots the income share of the bottom $100q$ percent of the

Figure 2 Generalized Lorenz curve. Source: Reproduced from Navas-Walt, C., Proctor, B.D., Lee, C.H., 2012. U.S. Census Bureau, Current Population Reports, P60–243, Income, Poverty, and Health Insurance Coverage in the United States: 2011. U.S. Government Printing Office, Washington, DC (Appendix Table A2). Online. Available at: www.census.gov/prod/2012pubs/p60-243.pdf (accessed 31.07.13.).

population against q and the diagonal line depicts a hypothetical distribution of perfect equality. It is clear that for each q the share was smaller in 2011 than it was in 1971 – the 1971 distribution Lorenz-dominates that for 2011. This simple intuitive notion of greater inequality conforms exactly to a fundamental principle to be explained below.

A further simple result emerges from this diagram. Take the area trapped between the Lorenz curve and the equality diagonal. Using eqns [7] and [9], we can show that the ratio of this area to the area of the whole triangle is given by the weighted sum $\sum_{i=1}^{n} \kappa_i x_{[i]}$, where the weights are $\kappa_i = [2i - 1 - n]/[n\mu(\mathbf{x})]$. This is exactly the Gini coefficient eqn [5].

Axioms

An inequality index I is in some ways like a utility function in consumer theory: it is a representation of an inequality ordering on the members of X and is usually taken to be continuous and ordinal – although there is often a 'natural' cardinal representation of a particular index, a formal argument for one representation rather than another is not usually provided (why not use the logarithm of the Gini coefficient, for example?). Ordinality is sufficient for making comparing income distributions, the primary task of inequality analysis. Axioms are essentially formal statements of the principles of assessment that are used to give meaning to the ordering represented by I. The treatment here does not claim to generality; rather, it focuses on those principles that are central to modern approaches to inequality. Rather than presenting the axioms as formal statements, however, it is more useful here to introduce the underlying key principles discursively.

Assume that everywhere in the following discussion, the vector $\mathbf{x}$ in eqn [1] is any arbitrary member of the set X.

- It is reasonable that the labeling of the components of $\mathbf{x}$ be irrelevant: it does not matter which income receiver gets which income. This means that I has the *symmetry* property:

$$I(x_1, x_2, \ldots, x_n) = I(x_2, x_1, \ldots, x_n) = I(x_3, x_1, \ldots, x_n) = \ldots \quad [10]$$

We will always assume that this holds and we may therefore adopt the convention that incomes have been labeled such that $x_1 \leq x_2 \leq \ldots \leq x_{n-1} \leq x_n$.

- Second, it is necessary to have a coherent way of characterizing inequality in different-sized populations. Perhaps the most obvious assumption is that simple replications of

Figure 3 Lorenz curve. Source: Navas-Walt, C., Proctor, B.D., Lee, C.H., 2012. U.S. Census Bureau, Current Population Reports, P60–243, Income, Poverty, and Health Insurance Coverage in the United States: 2011. U.S. Government Printing Office, Washington, DC, (Appendix Table A2). Online. Available at: www.census.gov/prod/2012pubs/p60-243.pdf (accessed 31.07.13.).

an income vector eqn [1] leave inequality unchanged. This is the *population principle*:

$$I(x_1, x_2, \ldots, x_n) = I(x_1, x_1, x_2, x_2, \ldots, x_n, x_n) = I(x_1, x_1, x_1, x_2, x_2, x_2, \ldots, x_n, x_n, x_n) = \ldots \quad [11]$$

Taken in conjunction with symmetry this allows one to represent distributions purely in terms of a distribution function.

- A key assumption that is commonly invoked focuses on the effect on inequality of a hypothetical small income transfer. Suppose $x_i < x_j$ and consider some positive number δ such that $x_i - \delta \geq \underline{x}$, then the *principle of transfers* (Dalton, 1920) requires that

$$I(x_1, \ldots, x_i, \ldots, x_j, \ldots, x_n) < I(x_1, \ldots, x_i - \delta, \ldots, x_j + \delta, \ldots, x_n) \quad [12]$$

  - a poorer-to-richer income transfer will always increase inequality.
- As a counterpart to the assumption relating to different sizes of population (eqn [11]), it is useful to have an assumption relating to different amounts of total income. The standard assumption is that of *scale independence*. This requires that for any scalar $\lambda > 0$,

$$I(\lambda x_1, \lambda x_2, \ldots, \lambda x_n) = I(x_1, x_2, \ldots, x_n) \quad [13]$$

  - double all incomes or halve all incomes and inequality is left unaltered. An alternative assumption that is sometimes used is *translation independence*. Take any real number δ such that $x_1 + \delta \geq \underline{x}$; then

$$I(x_1 + \delta, x_2 + \delta, \ldots, x_n + \delta) = I(x_1, x_2, \ldots, x_n) \quad [14]$$

  - add or subtract one dollar from every income and inequality is left unaltered.

Clearly this brief list raises some important questions. Why use these particular axioms? Some of them appear to be quite strong; for example, although scale independence seems attractive if the 'incomes' x_i here are measured in dollars and we consider just dividing through by some rate of exchange so as to work with incomes in some other monetary units, it may seem less attractive if one wishes to examine the impact on inequality of redistribution policies at different stages of economic growth: a rearrangement of income shares that constitutes a reduction in inequality in a low-income society might not be considered as a reduction in inequality if the whole population is prosperous. Furthermore, the axioms captured by eqns [10]–[13], for example, are satisfied by both eqns [4] and [5] as well as other important classes of inequality measures; on the other hand, the axioms captured by eqns [10]–[12] and [14] are satisfied by eqn [3] and another rich class of inequality measures. Following on from this question, what more is required to get a specific index or well-defined

family of indices that is both theoretically appropriate and practical to implement?

To answer this, we need to be precise about what it means to say that one distribution is more unequal than another and the intellectual basis used for making such comparisons. The meaning of inequality can be further clarified through one of several routes: this article will analyze three of these in turn, namely, social welfare, decomposition, and income differences.

Social Welfare and Inequality

The welfare-economic approach to the subject starts from the position that distributional equality is socially desirable so that inequality is essentially the opposite of welfare. If we adopt this approach then a natural definition of inequality follows. The idea is similar to the conventional measurement of economic waste and the basis for a simple but precise model can be established with only a little more theorizing. Here 'income' is used as shorthand for a comprehensive measure of individual well-being and is assumed to be non-negative.

The *social welfare function* (SWF) is a real-valued function W defined on the space of distributions X. The social welfare associated with a particular income distribution eqn [1], given by

$$W(x_1, x_2, \ldots, x_n), \qquad [15]$$

is to be interpreted as follows: suppose we are given a specific SWF $W(\bullet)$ and that for two separate income distributions $\mathbf{x}'$ and $\mathbf{x}''$, we have $W(\mathbf{x}') > W(\mathbf{x}'')$; then social welfare associated with the distribution $\mathbf{x}'$ is higher than the social welfare associated with the distribution $\mathbf{x}''$. In principle, W is an ordinal function so that the scale of measurement of welfare levels can be subjected to arbitrary monotonic increasing transformations.

This basic specification raises a number of important questions:

- Why express social welfare as a function of income? Income defined how?
- What particular form should W take?
- What is the relation between the functions I and W?

The answer to the first question helps to pin down the relationship between inequality measurement as conventionally practised and standard welfare economics – see Section Welfare and Income. The answers to the last two questions will determine the form of a class of inequality measures and permit us to establish some important welfare-economic results: these are addressed in Sections Social Welfare and Inequality Measures and Ranking Distributions.

Welfare and Income

Let us examine an issue that was sidestepped in the discussion of the example of Tables 1 and 2: how to do the trick of passing from a distribution of dollar income among households to a standard welfare analysis that is typically concerned with the levels of economic well-being of individuals. The standard approach is as follows. We require a method of appropriately capturing the relationship between the living standard that is attainable by an individual and the income that he/she is presumed to have access to within the household. This is conventionally done by defining a function $\nu(\bullet)$ that has as its argument a list of nonincome attributes $\mathbf{a}$ that might include household size, age, and sex of household members and health status; $\nu(\mathbf{a})$ determines the number of *equivalent adults* in the household with attributes $\mathbf{a}$ such that

$$x = \frac{y}{\nu(\mathbf{a})}, \qquad [16]$$

where y is nominal income and x is *equivalized income* that is taken to be comparable across different household types. Note that the equivalization function ν is typically specified as independent of income although this simplification is not essential; of course, the way in which the function ν is determined – from ethical considerations or econometric studies – is an important issue in its own right, but one that lies outside the present discussion. The function ν transforms a distribution of dollar incomes among n households

$$\mathbf{y} = (y_1, y_2, \ldots, y_n) \qquad [17]$$

into a distribution of equivalized incomes by households given by eqn [1]. In order to complete the welfare interpretation, we need to recognize that social welfare considerations are usually represented in terms of individuals rather than households, and so, for example, households consisting of couples should receive more weight in social welfare evaluations than households consisting of single individuals. Therefore, if the income-receiving units consist of households of differing size, we might want to represent this by introducing a corresponding set of population weights w_i for the observations, so that the distribution becomes an ordered list of pairs:

$$((w_1, x_1), (w_2, x_2), \ldots, (w_n, x_n)) \qquad [18]$$

where w_i is the number of persons in household i divided by the number of persons in the whole population. There is little analytical complication in using eqn [18] rather than eqn [1] as a representation of the distribution of equivalized incomes by individuals. Typically, it is just a matter of a minor redefinition of formulas for inequality measures and the like; for example, the coefficient of variation eqn [4] would now be written

$$\sqrt{\sum_{i=1}^{n} w_i \left[\frac{x_i}{\mu} - 1\right]^2} \qquad [19]$$

where μ is the appropriately redefined mean $\sum_{i=1}^{n} w_i x_i$. The method generalizes any inequality measure that can be written in the form $\Phi\left(\frac{1}{n}\sum_{i=1}^{n}\phi(x_i), \mu\right)$ just needs to be rewritten as $\Phi(\sum_{i=1}^{n} w_i \phi(x_i), \mu)$.

However, having introduced this important theoretical qualification, we will now set it aside – for expositional purposes it is convenient to assume (1) that the population consists of isolated individuals that are identical in every relevant respect other than income and (2) that income appropriately represents individual welfare. So, from here on, i indexes individuals or households and the distinction between x and y is dropped.

Social Welfare and Inequality Measures

The idea of the SWF was introduced without discussing specific properties of the function W. Some properties must be imposed on W if we require there to be a specific relationship

between social welfare and inequality and we impose specific assumptions on the function I. However, in addition it is particularly important to be explicit about how W should respond to an increase in one or more incomes. This is the usual principle that is applied:

- Suppose we consider any income distribution $(x_1, x_2, \ldots, x_n)$ and some positive number δ. Then *monotonicity* requires that

$$W(x_1, x_2, \ldots, x_i + \delta, \ldots, x_n) > W(x_1, x_2, \ldots, x_i, \ldots, x_n) \qquad [20]$$

On the assumption that monotonicity holds and that W is a continuous function, the SWF can itself be used to derive a family of inequality measures. There are several ways of doing this, but a standard approach is to represent social welfare using a money metric: we can always do this in view of the ordinal nature of W and the requirement that it be monotonic and continuous. The *equally distributed equivalent* (EDE) income is a real number ξ such that for any $(x_1, x_2, \ldots, x_n)$ in X:

$$W(\xi, \xi, \ldots, \xi) = W(x_1, x_2, \ldots, x_n) \qquad [21]$$

Clearly the relationship eqn [21] can be used to derive EDE as a function of the income distribution, $\xi(\mathbf{x})$; so the function $\xi(\cdot)$ is itself a valid way of representing social welfare.

Suppose we require that the principle of transfers apply to W; this by analogy with eqn [12] means that a mean-preserving poorer-to-richer income transfer will *de*crease social welfare. Then it is always true that $\xi(\mathbf{x}) \leq \mu(\mathbf{x})$ and the normalized gap between ξ and μ provides a natural basis for an inequality index

$$1 - \frac{\xi(\mathbf{x})}{\mu(\mathbf{x})} \qquad [22]$$

It is clear that this index is bounded between zero and one and that if there were perfect equality then we would have $\xi(\mathbf{x}) = \mu(\mathbf{x})$ and inequality in eqn [22] would be zero.

Furthermore, if the scale-independence property eqn [13] is also satisfied, then EDE income takes the form of a generalized mean:

$$\xi(\mathbf{x}) := \left[\frac{1}{n}\sum_{i=1}^{n} x_i^{1-\varepsilon}\right]^{\frac{1}{1-\varepsilon}}, \varepsilon > 0 \qquad [23]$$

and eqn [22] gives the class of *Atkinson indices*:

$$I_{\mathrm{A}}^{\varepsilon}(\mathbf{x}) := 1 - \left[\frac{1}{n}\sum_{i=1}^{n}\left[\frac{x_i}{\mu(\mathbf{x})}\right]^{1-\varepsilon}\right]^{\frac{1}{1-\varepsilon}}. \qquad [24]$$

(The limiting forms of eqns [23] and [24] as $\varepsilon \to 1$ are, respectively, $\xi(\mathbf{x}) = \exp\left(\frac{1}{n}\sum_{i=1}^{n} log(x_i)\right)$ and $I_{\mathrm{A}}^{1}(\mathbf{x}) = 1 - exp\left(\frac{1}{n}\sum_{i=1}^{n} log(x_i)\right)/\mu(\mathbf{x})$.)

The number ε is a parameter that characterizes individual members of the class of inequality measures; it is the degree of (relative) inequality aversion associated with the particular member of the class. For any given unequal income distribution, the larger is ε the larger is the Atkinson inequality index – there is an example of this in Table 3 below. There is a close analogy with a class of risk indices in the case of constant relative risk aversion. This is unsurprising since this approach

Table 3 Inequality indices for the example in Table 2

	1971	*2011*
$I_{\mathrm{A}}^{0.25}$	0.068	0.101
$I_{\mathrm{A}}^{0.5}$	0.138	0.198
$I_{\mathrm{A}}^{0.75}$	0.214	0.300
I_{A}^{1}	0.309	0.443
I_{Gini}	0.396	0.477
I_{GE}^{0}	0.370	0.585
I_{GE}^{1}	0.273	0.422

was explicitly founded on the formal similarity between distributional comparisons in terms of inequality and of risk (Atkinson, 1970).

If, instead of the scale-independence property, we required I to satisfy translation independence eqn [14], then we would obtain a different class of indices

$$I_{\mathrm{K}}^{\beta}(\mathbf{x}) := \frac{1}{\beta}\log\left(\frac{1}{n}\sum_{i=1}^{n} e^{\beta[x_i - \mu(\mathbf{x})]}\right) \qquad [25]$$

where $\beta > 0$ is a sensitivity parameter indexing members of the class (Kolm, 1976). The connection of eqn [25] with constant absolute risk aversion is evident. There are other 'regularity' assumptions that could be used, apart from than scale or translation independence – see Bossert and Pfingsten (1990).

Ranking Distributions

As noted earlier, there are important results available about welfare and inequality comparisons that do not require the usage of specific indices. They follow from standard first- and second-order dominance results that are familiar from finance and other disciplines. Take the special class of *additive* welfare functions where W in eqn [15] can be written in the form $\sum_{i=1}^{n} u(x_i)$ for some function u. If W is additive and satisfies the monotonicity axiom, then u must be a strictly increasing function; if, furthermore, W satisfies the principle of transfers, then u must be strictly concave. Then the following powerful results are available for any two distributions $\mathbf{x}'$ and $\mathbf{x}'' \in X$:

- *First order*: $\mathbf{x}'$ strictly Parade-dominates $\mathbf{x}''$ if and only if $W(\mathbf{x}') > W(\mathbf{x}'')$ for any additive W that satisfies the principle of monotonicity.
- *Second order*: $\mathbf{x}'$ strictly GLC-dominates $\mathbf{x}''$ if and only if $W(\mathbf{x}') > W(\mathbf{x}'')$ for any additive W that satisfies monotonicity and the principle of transfers (Shorrocks, 1983).

From the statement of these results, it is clear that the Parade- and GLC-dominance criteria are formally equivalent to first- and second-order stochastic dominances in the analysis of probability distributions.

A version of the second-order result applies to the conventional Lorenz curve and it accords with the intuitive argument presented in the introduction. Take the class of SWFs that satisfies the principle of transfers (they do not have to be

additive). Then, for two distributions $\mathbf{x}'$ and $\mathbf{x}''$ that have the same mean, the statement $W(\mathbf{x}') > W(\mathbf{x}'')$ 'for any W in this class' is true if and only if $\mathbf{x}'$ strictly Lorenz-dominates $\mathbf{x}''$. Furthermore, under these circumstances for any inequality index I that satisfies the principle of transfers it must be the case that $I(\mathbf{x}') < I(\mathbf{x}'')$. The implication of this is that all inequality measures that satisfy the principle of transfers 'go the same way' if one distribution Lorenz-dominates the other. This is illustrated in Table 3 (which again uses the distribution of household income by households). Rows one to four give the results for the Atkinson indices: notice that in each case measured inequality is closer to one (the maximum), the higher is the degree of inequality aversion. The indices in the last two rows of Table 3 are discussed in the next section.

Decomposition

The axioms discussed in Section Axioms induce some structure on inequality measures. By introducing the idea of *decomposing* inequality, we can impose more structure and thereby obtain a useful class of indices. There are two principal types of decomposition: by subgroups of the population (regions, age groups, etc.) and by components of income (labor income, income from capital, etc.) – see Cowell and Fiorio (2011). Here we focus on the population-subgroup issue.

Imagine that the population of n persons can be partitioned into a collection of m groups so that any individual falls into just one of these m groups. Each group j could be considered as a subpopulation of size n_j in its own right (the groups are exhaustive so that $\sum_{j=1}^{m} n_j = n$) and one could compute inequality within this subpopulation as

$$\iota_j = I(\mathbf{x}_j) \qquad [26]$$

where $\mathbf{x}_j$ is the income distribution consisting of just the members of subgroup j. The essence of the decomposition problem is to represent inequality overall as a function of inequality in each group $j = 1, \ldots, m$.

$$I(\mathbf{x}) = F(\iota_1, \iota_2, \ldots, \iota_m; \pi_1, \ldots, \pi_m, s_1, \ldots, s_m) \qquad [27]$$

where F is an aggregation function and the terms after the ';' show that aggregation may depend on the groups' shares of the population $\pi_j = n_j/n$ and the groups' shares of total income $s_j = n_j\mu(\mathbf{x}_j)/n\mu(\mathbf{x})$. A consistency requirement on eqn [27] is that, if the income distribution within subgroup j changes so as to increase ι_j in eqn [26], all other things remaining the same, then inequality overall should increase. Insisting on this requirement on F for all logically possible partitions induces a type of separability on the function $I(\cdot)$ so that the index must be of the general form mentioned just after eqn [19] above. If we also require that scale-independence hold, then the inequality index must take the specific form

$$I_{\mathrm{GE}}^{\alpha}(\mathbf{x}) := \frac{1}{\alpha^2 - \alpha}\left[\frac{1}{n}\sum_{i=1}^{n}\left[\frac{x_i}{\mu(\mathbf{x})}\right]^{\alpha} - 1\right] \qquad [28]$$

or some monotonic transform of it, where α is a real number. The 'GE' used in the labeling of eqn [28] stands for the *generalized entropy* class, which is a generalization of the two indices introduced by Theil (1967). Theil's two indices are those corresponding to the special forms in the cases $\alpha = 0$ and 1, namely

$$I_{\mathrm{GE}}^{0}(\mathbf{x}) := -\frac{1}{n}\sum_{i=1}^{n}\log(x_i/\mu(\mathbf{x})) \qquad [29]$$

and

$$I_{\mathrm{GE}}^{1}(\mathbf{x}) := \frac{1}{n}\sum_{i=1}^{n}[x_i/\mu(\mathbf{x})]log(x_i/\mu(\mathbf{x})) \qquad [30]$$

The values of these indices for the US example are given in the last two rows of Table 3. The α in eqn [28] is a parameter that characterizes different members of the GE class: a high positive value of α yields an index that is very sensitive to income transfers at the top of the distribution; specifying a negative value will produce an index that is sensitive to income transfers among the poor. Members of the GE class can only handle negative incomes if α is an integer greater than or equal to 2; if α is greater than or equal to 1 the GE index can handle zero incomes.

Finally note that there is a functional relationship between the class eqn [24] and the class eqn [28]. If we set $\varepsilon = 1 - \alpha$ then, long as $\alpha < 1$, we have

$$I_{\mathrm{A}}^{\varepsilon}(\mathbf{x}) = 1 - \left[1 + \alpha[\alpha - 1]I_{\mathrm{GE}}^{\alpha}(\mathbf{x})\right]^{1/\alpha} \qquad [31]$$

Income Differences

The third way forward from the basic argument outlined in Section Axioms focuses on fundamental income differences. This is one of the key ways in which one can motivate usage of the very well-known inequality indices mentioned in Section Indices. The variance and the coefficient of variation eqn [4] can be thought of as a representation of the averaged squared difference between each income x_i and the mean. A compelling argument for the Gini coefficient is that it is the (normalized) expected value of the absolute difference between any two randomly selected incomes in the population.

However, there are other types of income difference that are of special relevance to inequality measurement. Just as some poverty indices can be characterized as a kind of average distance of individual incomes from a reference income level – the poverty line (many poverty indices can be written in the form $\frac{1}{n}\sum_{i=1}^{n} p(z - x_i)$, where z is the poverty line and $p(\cdot)$ is a nondecreasing function that is zero for all $x_i \geq z$) – so also some inequality measures use the idea of a reference level income. In the case of inequality, the reference income level has been suggested as either that of the best-off person in society, or of the average income of all those who are better off than any given person i (Temkin, 1993). In each of these cases, application of standard axioms about the structure of inequality orderings leads to a class of inequality indices that bears a functional similarity to poverty indices and to indices of relative deprivation (Cowell and Ebert, 2004).

Implementation

The practical issues associated with the exposition of the example in Tables 1 and 2 highlight some of the problems in

implementing inequality measures and associated tools – the definition of income, income receiver, etc. Given the way in which income data are usually obtained, issues of sampling and measurement error usually need to be treated carefully. Furthermore, the special nature of income and wealth distributions and the sensitivity of inequality indices to very high or very low incomes usually require that particular attention be paid to the problem of outliers. Finally, it should be noted that it is still sometimes the case that the data required for estimating inequality indices are made available only in grouped form rather than as microdata so that special techniques may be required for interpolation within income intervals and for modeling the tails of the distribution.

Abstract

Although humans have existed for around 200 000 years, for most of their time on earth their societies were not characterized by much inequality. Despite some differentiation on the basis of age, gender, and kinship, people enjoyed relatively equal access to resources. Inequality begins to rise with the emergence of cities around 10 000 years ago, which yielded the first stratified class-based societies. Inequality rose quite dramatically with the industrialization and urbanization of society around 200 years ago, as more human interactions occurred in the context of markets. Because markets are socially embedded, different architectures for exchange, production, and consumption yield widely discrepant levels of inequality. Variations in equality reflect the degree to which categorical mechanisms of stratification, such as exploitation and opportunity, are built into societies and the markets they house, and the number and range of people who are subjected to nonmarket processes of discrimination and exclusion.

The Evolution of Inequality

Prior to the agricultural revolution, human societies generally were not stratified. People living in stratified societies are characterized by unequal access to material, symbolic, and emotional resources. Material resources include food, goods, income, and various accumulations of physical and financial capital. Symbolic resources include power, social capital, and cultural capital, which are often signified by physical tokens of status, prestige, and social standing. Emotional resources include warmth, attraction, liking, and love, both physical and emotional.

Until around 10 000 years ago the vast majority of human beings lived in small foraging groups of no more than 150 people. Foraging peoples sustain themselves through a combination of hunting and gathering, with the precise mix being determined by what food sources are available in the local environment (Kelly, 1995). In foraging societies, people are differentiated on the basis of age, gender, and kinship but not much else. Although foraging societies evince some stratification with respect to these characteristics, resources are generally distributed equally, especially when flora and small fauna constitute the main food sources. In societies where big-game hunting serves as a key food source, males typically garner more power and prestige within the group (Sanday, 1981); but even in these societies a variety of informal leveling mechanisms limit inequalities, enforcing equality through mechanisms such as shaming, ridicule, and ostracism on the negative side, and praise, kudos, and respect on the positive side.

The agricultural revolution created the first settled populations and led to the formation of cities and the first truly stratified societies. According to Fiske (1991), humans are capable of engaging in four fundamental relationships: communal sharing, equality matching, authority ranking, and market pricing. In communal sharing relationships, people have a common sense of identity, express weak individuality, and share resources with others on the basis of need. Equality matching occurs when peers are recognized as equals but are treated as distinct individuals who engage in tit-for-tat exchanges over time, such that any one person's inputs to the collective are ultimately matched by contributions from others.

Whereas communal sharing and equality matching predominate in foraging societies, the advent of cities brought about the proliferation of authority-ranking relationships (Fiske, 1991). Authority ranking occurs within a hierarchical social structure characterized by progressive upward inclusion within a relation of dominance. As one moves up the hierarchy, members at each successive rank dominate a larger number of subordinates occupying lower levels. A ranked category within any social structure is generally referred to as a class, and as noted earlier, members of different classes are characterized by unequal access to material, symbolic, and emotional resources.

Urbanism also created the potential for a fourth kind of human relationship – market pricing – in which value is determined by competition between people who supply and demand scarce goods, services, and resources (Fiske, 1991). Relationships in a market system are structured according to price, a universal metric by which people are able to compare themselves to each other and to judge the value of the things they exchange, no matter how dissimilar they might otherwise be. People who interact through market pricing value each others' actions, services, and products according to the price at which they can be exchanged.

Although urbanism created the potential for markets, market pricing was rather slow to evolve as a common human relationship. Although cities emerged around 10 000 years ago and quickly evolved quarters dedicated to barter (Chant and Goodman, 1999), the first coins were minted only 2700 years ago (Davies, 2002). With the invention of money, market pricing came into existence; but markets remained limited in scope until quite recently, being confined to the exchange of a small range of goods and services within urban areas. Prior to industrialization, only about 5% of any society's inhabitants lived in cities and most human relations occurred in small peasant villages with relationships dominated by communal sharing, equality matching, and authority ranking (Massey, 2005).

Although markets began to expand in the sixteenth century, it was not until the advent of industrialism and the urbanization of society in the nineteenth century that market pricing became a common form of human interaction. From AD 1800 onward, well-functioning markets for land, labor, capital,

 http://dx.doi.org/10.1016/B978-0-08-097086-8.32183-3

goods, information, and a myriad of services expanded within and between nations, ultimately creating a global economy that exposed people to market pricing on a daily basis. The emergence of the market economy was accompanied by a dramatic increase in material inequality, as the gap between the richest and poorest members of society expanded to unprecedented levels (Kuznets, 1955). Between AD 1850 and 1950, for example, the total value of goods and services produced throughout the world rose from $939 trillion to $5336 trillion (Maddison, 2001) and the largest private fortune in the United States rose from $1 million to $1.6 billion (Phillips, 2002).

Markets generate inequalities in income and wealth because of differences in productivity between individuals and variations in the scarcity of the things exchanged through markets. Differences in productivity reflect different endowments of human, social, physical, and financial capital whereas differences in scarcity reflect variation in the abundance of goods, services, and resources. More productive people earn higher incomes and owners of scarce commodities receive higher prices, thus producing inequalities with respect to income and wealth.

As indicated by the foregoing history, however, markets are a human invention, not a state of nature, and quite a recent one at that. Being of recent origin, markets evolved out of and are embedded within preexisting social structures, yielding a variety of different market 'architectures' (Hall and Soskice, 2001; Fligstein, 2001). Depending on how markets are socially constructed, widely divergent levels of inequality may be achieved. The degree of inequality ultimately produced by a market economy is thus socially determined. Across all human societies, inequality is produced by a combination of two simple but powerful social mechanisms: (1) the allocation of people to socially defined categories and (2) the creation of mechanisms that allocate resources unequally across categorical boundaries, producing what Tilly (1998) calls 'categorical inequality,' – a form of stratification that is remarkably 'durable' in the sense that it is reproduced over time and across generations (Massey, 2007).

The Psychological Foundations of Inequality

Stratification begins psychologically with the creation of cognitive boundaries that separate people into social groups. Before categorical inequality can be implemented socially, categories must be created cognitively to classify people based on observed or inferred characteristics. Categorical thinking is a characteristic feature of human cognition. Since human memory is finite, if the brain is to remember more it must combine pieces of information into sets of conceptual categories known as schemas, using common properties to classify a large number of people, objects, or experiences into a smaller number of readily identifiable mental constructs.

Schemas do not exist simply as neutral mental representations, but are typically associated with emotional valences. The human brain is composed of two parallel processors which, while interconnected, function independently (Carter, 1998; Panksepp, 1998). The 'emotional brain' is rooted in a set of neural structures that are common to all mammals and known collectively as the limbic system, whereas the 'rational brain' is centered in the prefrontal cortex and is by far the most developed in humans (Damasio, 1994, 1999). The two portions of the brain, (labeled System 1 and System 2 by Kahneman, 2011) are interconnected, but the numbers and speed of the neural connections running from the limbic system to the neocortex are greater than in the reverse connections. Therefore the emotions stored in the limbic system, which are typically unconscious or implicit, greatly affect how humans feel about categories that exist within the rational, conscious brain (LeDoux, 1996; Zajonc, 1998).

Emotions stored in the limbic system may be positive or negative but when they are associated with particular categories of people they contribute to prejudice, which is a predetermined emotional orientation toward members of other social categories (Fiske, 2003). A prejudicial orientation for or against a social group thus contains both conscious and unconscious components (Bargh, 1997). On the one hand, a person may be a principled racist who consciously believes that African-Americans are inferior. Another person may sincerely and overtly believe in racial equality but he may harbor a variety of anti-black sentiments and associations that are unconscious. These associations are created through conditioning in society; – for example, the repeated visual pairing of violent crime scenes with black perpetrators seen on television, creates an unconscious association between African-Americans and criminality.

All human beings whether they think of themselves as prejudiced or not, mentally construct schemas that classify people into categories based on age, gender, race, and ethnicity (Stangor et al., 1992; Fiske, 1998). Although stereotypes are always present, people are especially likely to fall back on them in making judgments when they feel challenged, face uncertainty, or experience a sensory overload (Bodenhausen and Lichtenstein, 1987). In making stereotypical judgments about other social actors, humans evaluate people along two fundamental dimensions: warmth and competence (Fiske et al., 2002). Warmth refers to how likable and approachable a person is. We are attracted to people we view as high on the warmth dimension and seek to interact and spend time with them. We find people who are low on the warmth dimension to be off-putting and generally avoid them, seeking to minimize the number and range of social contacts with them; we don't like them and find them 'cold.'

In addition to these subjective feelings of attraction and liking, we also evaluate people in terms of competence – their ability to act in a purposeful manner to get things done. We may or may not like people who are highly competent, but we generally respect them and admire their ability to achieve. These two dimensions of social perception define the stereotype content model, which holds that stereotyping involves the cognitive placement of groups and individuals in a two-dimensional social space defined by the intersection of the dimensions of warmth and competence, yielding four basic combinations that determine the content of social perceptions (Fiske et al., 2002).

People perceived as high in both warmth and competence include members of one's own social group as well as members of groups perceived to be similar to one's own. People who are warm and competent are approachable and worthy of respect and the relevant emotion associated with them is esteem or

pride. In addition to those perceived to be in and similar to the 'in-group,' the model defines three basic kinds of 'out-groups.' Those groups and individuals perceived to be competent but not warm are respected but not liked and the relevant emotion people feel toward them is envy. This category includes professionals and the rich, but also the classic middlemen minorities, such as Jews in Medieval Europe, the Chinese in Malaysia, and Indians in East Africa. In a stable social structure, people show public respect and defer to members of envied out-groups, but if the social order breaks down they may become targets of communal violence. Groups and individuals perceived to be warm but not competent include the disabled, the elderly, the blind, the mentally retarded – people who have experienced some misfortune but who are otherwise perceived as 'people like us' – so the relevant emotion for them is pity. In a stable social structure pitied out-groups are cared for; but in times of social disorder or scarcity they may suffer from neglect, though they generally do not become targets of communal violence. Finally, individuals and groups perceived as low in both warmth and low in competence include social outcasts such as junkies, drug dealers, sex offenders, and the homeless and the relevant emotion associated with them is disgust or scorn.

Recent work in neuroscience has implicated a particular region of the brain as central to the process of social cognition (see Harris and Fiske, 2006). Whenever individuals perceive a stimulus to be a human being and therefore a potential social actor, an area of the brain known as the medial prefrontal cortex lights up when observed under functional magnetic resonance imagery (fMRI). Harris and Fiske (2006) pretested a number of photographic images of social actors to establish the quadrant into which they fell; then they showed these images to experimental subjects so that each person saw a total of 80 images – 20 images of esteemed in-group members; 20 images from envied out-groups; 20 images of pitied out-group members; and 20 images of people from despised out-groups. As they viewed the various social images, the brains of subjects were scanned under fMRI and the centers of activity recorded.

As expected, the investigators found that images of people representing the in-group or others like them, triggered a clear reaction in the medial prefrontal cortex, as did images of envied out-groups and pitied out-groups. Startlingly, however, images of despised out-groups did not light up this brain region (Harris and Fiske, 2006). Whereas out-groups triggering feelings of pity and envy were instantly perceived as human beings and social actors, those that were despised were not seen in social terms at all at the most fundamental level of cognition. Despised out-groups are thus dehumanized at the neural level, giving other human beings license, in their own minds, to treat them as if they were animals or objects.

The Social Construction of Inequality

The position of a group within the social space defined by warmth and competence is not fixed but malleable, varying across time and space as well as across. Although social categories are ultimately constructed and maintained by individuals within their own minds, the process by which boundaries are expressed in society is quintessentially social. Group identities and boundaries are negotiated through repeated interactions that establish working definitions of the categories in question, including both objective and subjective content, a process that sociologists have labeled boundary work (Lamont and Molnar, 2002). When social actors succeed in establishing the limits and content of various social categories in the minds of others, psychologists refer to the process as framing (Kahneman and Tversky, 2000). In essence, boundary work involves defining social categories in the social structure and framing involves defining them in human cognition.

People naturally favor boundaries and framings that grant them greater access to materialistic, symbolic, and emotional resources and they seek to convince others to accept their favored version of social reality (see Lakoff, 2002). In general, social actors who control more resources in society – those toward the top of the stratification system – have the upper hand in framing and boundary work (Fiske, 2011). Thus whites historically have perpetuated negative stereotypes of African-Americans as unintelligent, violent, hypersexual, and shiftless; and rich people likewise have promoted a view of the poor as lazy, unmotivated, indisciplined, and undeserving, cognitively rendering both groups despicable and not worthy of consideration. To the extent that negative stereotypes become a part of everyday social cognition, individual members of 'cold' and incompetent out-groups will tend to experience mistreatment and inequality in society.

Given any set of cognitively framed and socially constructed categories and a population of people distributed among them, inequality is generated and perpetuated by two basic mechanisms: exploitation and opportunity hoarding (Tilly, 1998). Exploitation occurs when people in one social group expropriate a resource produced by members of another social group and prevent the latter from realizing the full value of the effort involved in producing it. Opportunity hoarding occurs when actors in one social group restrict access to a scarce resource, either through outright denial to members of other social groups or by exercising monopoly control that requires members of other groups to pay a rent in return for access (Tilly, 1998).

Within any social structure, exploitation and opportunity hoarding are, in turn, reinforced by two other social processes that work over time to institutionalize categorical distinctions and lock them into place (Tilly, 1998). The first is emulation, whereby one group of people copies a set of social categories and stratifying mechanisms from another group, or transfers the categories and mechanisms from one social setting to another. The second is adaptation, whereby social relations and day-to-day behaviors become oriented toward a set of ranked categories, so that decisions about who to befriend, who to help, who to share with, who to live near, who to court, and who to marry are made in ways that assume the existence and importance of asymmetric distinctions. According to Tilly (1998: 10), "exploitation and opportunity hoarding favor the installation of categorical inequality, while emulation and adaptation generalize its influence."

Social Inequality in Practice

In the developed societies of today, inequality is produced by categorical mechanisms of exploitation and opportunity

hoarding embedded within social structures that organize and shape markets, thereby conditioning the market outcomes experienced by different social groups. In the United States, categorical distinctions on the basis of class, race, and gender have historically served to generate inequality, though the precise nature of these dimensions have shifted over time (Massey, 2007). Until the 1960s the starkest inequalities were produced along the lines of race by socially structured exclusion and discrimination, which were built into US markets and infused into American social practices.

The institution of slavery represents the harshest possible system for socially constructing exploitation and opportunity hoarding. In the United States, persons of African origin historically have been defined socially as a despised and scorned out-group, thus rendering them cognitively suitable for systematic discrimination and exclusion. Until AD 1865 they were subject to a set of formal and informal social institutions – public laws and private practices as well as shared expectations and individual prejudice – that enslaved Africans and compelled them to work for little more than sustenance while excluding them from virtually all sources of well-being in society, including income, health, wealth, and all forms of capital.

After the Civil War, slavery in the South was replaced by a new system of exploitation and opportunity hoarding known as 'Jim Crow.' To replace slavery an alternative set of formal laws and informal practices were established to confine African-Americans to a system of debt peonage and exclude them all but the most menial occupations, while paying them below-market wages, subjecting them to separate and unequal circumstances across all venues, and controlling their behavior through high levels of violence, both vigilante and state-sanctioned (Packard, 2003). In the North, segregation was *de facto* rather than *de jure*, as African-Americans were residentially confined to ghettos created through institutionalized practices of discrimination and through exclusion from real estate and banking services (Massey and Denton, 1993). As the state assumed a larger role in the political economy during the 1930s, African-Americans were also systematically excluded from the resources and protections of the New Deal (Katznelson, 2005).

During the 1960s and 1970s, of course, Civil Rights legislation eliminated the legal foundations of Jim Crow and overturned the racial exclusions of the New Deal. The 1964 Civil Rights Act outlawed discrimination in labor markets and the provision of services, and promoted school desegregation; the 1965 Voting Rights Act enfranchised black voters; the 1968 Fair Housing Act banned discrimination in the rental and sale of housing; the 1974 Equal Credit Opportunity Act prohibited discrimination in lending markets; and the 1977 Community Reinvestment Act forbade the denial of credit to black neighborhoods. At the same time, President Lyndon Johnson's 'War on Poverty' channeled vast resources to formerly excluded groups (Quadagno, 1994).

As a result of these legislative reforms, black employment, earnings, and educational achievement rose and levels of residential segregation declined. Despite these improvements, however, gaps in socioeconomic status persist; and progress toward racial equality eventually stagnated in the wake of a white counter-reaction (Bobo et al., 1997; Sharkey, 2012). Although segregation declined in small metropolitan areas with small black populations, it remains high in large areas with large black populations and racism continues to play an active role in promoting black spatial isolation (Rugh and Massey, 2013). At the same time, new mechanisms of racial exclusion have evolved, with restrictive density zoning emerging as the primary barrier to integration across metropolitan areas (Rothwell and Massey, 2009).

Although civil rights laws have eliminated overt racial discrimination in most markets, surreptitious discrimination nonetheless continued to be documented by audit studies (Blank et al., 2004). Moreover, beginning in the 1980s, a new, racialized system of criminal justice evolved to produce extreme rates of incarceration for African-Americans, especially those who were young, male, and lacked a college education (Alexander, 2010). The rising prevalence of criminal records among young black males, in turn, put them at a severe disadvantage competing in markets and gaining access to social resources, while straining families and social organizations in the black community (Western, 2006; Pager, 2007).

Other racial and ethnic groups also have historically experienced exploitation and exclusion from opportunity in the United States, though not to the same extent as African-Americans. Asian immigrants were excluded by discriminatory immigration legislation for most of the twentieth century; were denied full access to citizenship (Zolberg, 2006); were confined to their own residential enclaves (Tsui, 2009); and under certain circumstances interred in camps (Daniels, 1993). Immigrants from Southern and Eastern Europe also faced restrictive immigration quotas after 1920 (Zolberg, 2006) and ensuing generations struggled to be accepted as White (Roediger, 1991). Following the Treaty of Guadalupe Hidalgo in 1848, persons of Mexican origin were subjected to systematic exploitation and exclusion throughout the American Southwest, resulting in high levels of residential segregation, low levels of education, meager earnings (Grebler et al., 1970), and widespread skin color discrimination in markets (Telles and Murguía, 1992).

Although exploitation and exclusion directed at persons of Southern European, Eastern European, and Asian origin have faded in recent years to yield rough parity with mainstream Americans (Alba and Nee, 2003), Mexicans paradoxically have come to experience higher levels of discrimination and exclusion in recent years, owing to the rise of the US immigration system as a powerful race-making institution (Massey, 2013). The curtailment of opportunities for legal entry after 1965, produced a rise in illegal migration and the propagation of a 'Latino Threat Narrative' in public discourse and the media (Chavez, 2008). The demonization of Latinos hardened public opinion against Mexicans in particular and Hispanics in general and spurred a militarization of the Mexico–US border, a policy that only served to cut off circulatory migration and increase the size of the undocumented population in the United States (Massey and Pren, 2012). The rising number and increasing geographic spread of illegal immigrants in the context of recession and unemployment unleashed a new wave of repressive policies and negative framing that steadily pushed Latinos into the despised quadrant of social cognition (Lee and Fiske, 2006), down the socioeconomic hierarchy (Massey, 2007), and toward higher levels of segregation (Rugh and Massey, 2013).

Gender has also served historically as a prominent dimension of stratification in the United States. Women were denied the right to vote until 1920, could not enter into private contracts without a husband's approval in many states until the 1960s, were systematically excluded from many occupations until well into the civil rights era (Massey, 2007), and they continue to earn less than men with similar qualifications, especially in female-dominated occupations (England et al., 2001; Bobbit-Zeher, 2011). Although overt discrimination against women is now illegal, covert gender discrimination has persisted in many markets (Darity and Mason, 1998; Goldin and Rouse, 2000) and the earnings gap increases with rise in occupational status (2001). Meanwhile, occupational segregation by gender remains quite high (Charles and Grusky, 2004) and the differential distribution of men and women across occupational categories explains a large part of the gender gap in earnings (Blau and Kahn, 2006).

Finally, class is the critical third dimension of categorical inequality in the United States and it has also undergone significant change in recent decades. Whereas inequalities by gender and race have generally decreased, though at times quite slowly, class divisions have unambiguously widened. Residential segregation by income and education have increased (Massey et al., 2009) and inequality with respect to wealth and income have skyrocketed since the 1970s (Piketty and Saez, 2003; Wolff, 2010; Alvaredo et al., 2013) in response to deliberate policy actions that have served to harm low and middle income people while benefiting the rich (Bartels, 2008). The real value of the minimum wage has been allowed to decline to the lowest level in decades; public spending on benefits and services to the poor has flagged; federal income transfers and food subsidies have been severely curtailed;, and consumer debt has risen and surged to widen the gap between overall interest rates and credit card interest rates. At the same time, tax rates on top incomes and capital gains have been reduced to the lowest levels since the 1920s (Massey, 2007). As a result, whereas pretax inequality in the United States is no greater than in other developed nations (and in several cases is less) once taxes are taken into account, income inequality in the United States is by far the highest (Smeeding, 2005) – thus pointing to the social origins of inequality in the United States (Massey, 2009).

EDITOR IN CHIEF BIOGRAPHY

James D. Wright received his bachelor's degree in philosophy from Purdue University in 1969, a master's degree in sociology from the University of Wisconsin in 1970, and his PhD in sociology from Wisconsin in 1973. His first academic appointment was at the University of Massachusetts, Amherst, where he was promoted to Associate Professor in 1976 and to Full Professor in 1979. Most of his 15 years at Massachusetts were spent as Director, Associate Director, or Director of Research in the Social and Demographic Institute.

Wright left Massachusetts for Tulane University in New Orleans in 1988 where he served as the Charles and Leo Favrot Professor of Human Relations in Tulane's Department of Sociology. He also enjoyed a courtesy appointment in the Tulane School of Public Health, Department of Biostatistics and Epidemiology. He left Tulane in 2001 to become the Provost's Distinguished Research Professor of Sociology at the University of Central Florida. In 2003, he was named as the Director of the University's Institute for Social and Behavioral Sciences and in 2013, was designated as a UCF Pegasus Professor, the University's highest faculty honor.

Wright was the Editor in Chief of the scholarly journal *Social Science Research* from 1978 until 2014. His previous editing experience also includes a 20-year stint as editor of the Aldine de Gruyter book series *Social Institutions and Social Change*, two editions of the *Handbook of Survey Research* (Academic Press, 1983; Emerald Publishing, 2010), and service on the editorial boards of numerous journals. He is the author of 21 books and scholarly monographs on topics ranging from homelessness to research methods to NASCAR, and he has published more than 300 journal articles, book chapters, reviews, essays, and polemics. Wright lives with his wife Christine Stewart and their multiple dogs and cats in Winter Springs, Florida, where in his spare time he likes to cook fancy meals for large crowds.

PREFACE TO THE FIRST EDITION

Large and ambitious works such as the present Encyclopedia depend on countless instances of input, cooperation, and contextual support. Therefore, the editors in chief would like to express their gratitude to several institutions and individuals. Our most general thanks go to our respective home institutions, the Center for Advanced Study in the Behavioral Sciences, Stanford, and the Max Planck Institute for Human Development, Berlin. We are certain that without the effective infrastructures of these institutions and the rich collegial networks and intellectual climate they provide, implementing this Encyclopedia in such a short amount of time would not have been possible. In this context, we also need to mention that due to the administrative budgets provided to the editors in chief by the publisher, the financial strains on our home institutions were minimal. Such a situation may be a rarity in the modern world of scientific publishing where publishers often press scholars and institutions into taking on larger and larger shares of the publication enterprise.

Aside from the more than 4000 authors, our deepest thanks goes to the editors of the 39 sections, to whom we delegated many decisions at various stages, who were primarily responsible for developing the lists of articles and authors, and who stood as the main gatekeepers of scientific quality for the entries in their sections. As a group, the section editors displayed remarkable energy, intelligence, and tolerance for the inevitable frustrations of tending large numbers of authors over a long period of time. Because of the brevity of the acknowledgment of the main editorial coproducers here, we alert the reader to the list published as part of the front matter and the description of their extensive work we offer in the Introduction. We would also like to mention that one of our highly esteemed section editors, Franz Weinert, died unexpectedly during the last phases of his editorial work. For people who had the pleasure of knowing Franz Weinert, it comes as no surprise that he completed his editorial duties without ever complaining about the difficult health conditions he was facing. He was a gentleman and a distinguished scholar.

The International Advisors also gave wise counsel on several designated occasions, and a number of these scholars represented on the International Advisory Board took more initiative — always helpful — than we had originally asked. The International Advisory Board was particularly helpful in the process of choosing section editors. Some of its members assisted us ably as we attempted to make the Encyclopedia as international as possible and also in dealing with special problems that are part of a large project with close timelines. Thus, we remember a few occasions where members of the International Advisory Board helped us with their substantive and social competence to deal with matters of editorial disagreements. Because of the overall quality, collaborative spirit, and professional responsibility of our section editors, these events were rare indeed, but dealing with them required masterful and accelerated input. We appreciate the collegiality that members of the Board displayed when called upon in these special circumstances.

In addition, and as described in the Introduction, there was a host of esteemed colleagues who gave us advice on numerous questions such as author and editor selection, organizational matters, topics for entries, content and quality of selected articles, substantive and methodological niches to be covered, as well as last-minute author replacements. The number of such individuals is large indeed, and most likely, significantly larger than the list presented below. There were too many short, but nevertheless significant collaborative encounters that we likely did not deposit into our long-term memory or written documentation. We apologize for such oversights.

In this spirit, we appreciate the advice given in the three planning meetings in Stanford, Uppsala, and Dölln/Berlin by the following scholars: Peter Behrens, Burton Clark, Gordon Clark, Lorraine Daston, Meinolf Dierkes, Jean-Emile Gombert, Torsten Husén, Gérard Jorland, Ali Kazancigil, Wolfgang Klein, Gardner Lindzey, Renate

Mayntz, Andrew Pettigrew, Denis Phillips, Marc Richelle, Ursula M. Staudinger, Piotr Sztompka, Eskil Wadensjö, Björn Wittrock, and Robert Zajonc.

We would like to extend special thanks to Laura Stoker, who pinch-hit for Nelson Polsby (section editor for Political Science) who was unable to attend the meeting of section editors in April 1998; and to Linda Woodhead, Senior Lecturer in Religious Studies, Lancaster University, who assisted David Martin with editorial work at all phases for the section on Religious Studies.

We also acknowledge the help of scholars who advised Smelser and Baltes at the stage of pulling together the entry lists, proposing authors, and occasionally reviewing the content and quality of articles submitted.

Smelser thanks: Jeffrey Banks, Peter Bickel, Edgar Borgatta, Charles Camic, Jennifer Chatman, Jean Cohen, Michael Dear, Pierre Ducrey, Eckart Ehlers, Sylvie Faucheux, Steven Guteman, Frank Furstenberg, Helga Haftendorn, Peter Katzenstein, David Laibson, Stephan Lauritzen, Douglas McAdam, Eleanor Maccoby, Phyllis Mack, Cora Marrett, Douglas Massey, Donald Melnick, Harvey Molotch, Lincoln Moses, James Peacock, Trond Petersen, Andrew Pettigrew, Alejandro Portes, Matilda Riley, István Rév, John Roberts, Dorothy Ross, Rob Sampson, Fritz Scharpf, Melvin Seeman, James Short, Fritz Stern, Carol Swain, Ann Swidler, Ken'ichi Tominaga, Charles Tilly, Wolfgang van den Daele, Sidney Verba, Margaret Weir, Thomas Weisner, and Jennifer Wolch.

Baltes is very grateful to: Nancy Andreasen, Gerhard Arminger, André-Jean Arnaud, Jens Asendorpf, Jan Assmann, Margret Baltes (deceased), Jürgen Baumert, Peter Behrens, Manfred Bierwisch, Niels Birbaumer, Peter Bloßfeld, Walter Borman, Robert F. Boruch, Mark Bouton, Michael Bratmann, David Buss, Shelley Chaiken, Lorraine Daston, Juan Delius, Marvin Dunnette, Georg Elwert, Helmut Fend, Hans Fischer, Peter Frensch, Alexandra M. Freund, Dieter Frey, Jochen Frowein, Gerd Gigerenzer, Snait Gissis, Peter Gollwitzer, Ian G. Gotlib, David Gyori, Heinz Häfner, Helga Haftendorn, Giyoo Hatano, Adrienne Héritier, Theo Herrmann, Otfried Höffe, Ludger Honnefelder, Paul Hoyningen-Huene, James Huang, Günther Kaiser, Heidi Keller, Martina Kessel, Gábor Klaniczay, Wolf-Hagen Krauth, Achim Leschinsky, Karen Li, Shu-Chen Li, Ulman Lindenberger, Elizabeth Loftus, Gerd Lüer, Ingrid Lunt, Hans J. Markowitsch, Laura Martignon, Randolf Menzel, Dietmar Mieth, Susan Mineka, Setsuo Miyazawa, John R. Nesselroade, Claus Offe, Vimla Patel, Meinrad Perrez, Rosa Lynn Pinkus, Robert Plomin, Neville Postlethwaite, Thomas Rentsch, István Rév, Peter Roeder, Richard Rorty, Hubert Rottleuthner, Peter Schäfer, Heinz Schuler, Norbert Schwarz, Richard J. Shavelson, Joan E. Sieber, Burton Singer, Wolf Singer, Edward Smith, Hans Spada, Günter Spur, Rolf Steyer, Michael Stolleis, José Juan Toharia, LeRoy B. Walters, Elke U. Weber, Peter Weingart, and Reiner Wimmer.

There was one more group that played a special role in the editorial review (see also Introduction). Baltes was assisted by a team of colleagues who provided expert input to the section editors and to him during final review: Gregor Bachmann, Alexandra M. Freund, Judith Glück, Wolfgang Klein, Olaf Köller, Shu-Chen Li, Ulman Lindenberger, Ursula M. Staudinger, and Christine Windbichler. Their expertise in helping us to ensure quality is gratefully acknowledged.

The day-to-day organizational work of the editors in chief occurred at their respective research centers — the Center for Advanced Study in the Behavioral Sciences and the Max Planck Institute for Human Development in Berlin. Smelser singles out Julie Schumacher, his main assistant in the project, for her organization of the meeting of section editors, and her superb coordination of the flow of correspondence and manuscripts over several years. She remained firm when the rest of us were faltering, and displayed the greatest efficiency, intelligence, and good cheer. Smelser also relied on periodic help from Leslie Lindzey, Kathleen Much, Jane Kolmodin, and Anne Carpinetti. Michelle Williams of the University of California, Berkeley, served as his main editorial assistant for nearly 2 years, going over all entry manuscripts from the standpoint of readability, and carrying a great part of the cross-referencing work; her judgment was always the best, and Smelser is forever indebted to her.

At the Max Planck Institute for Human Development, and aside from Julia Delius (see below), Baltes expresses his deeply felt thanks to the main secretarial staff in his office (Helga Kaiser, Romy Schlüter, Conor Toomey) who during the preparation of this Encyclopedia took on larger shares of responsibilities for other projects and occasionally helped out when the editorial office was overloaded. More directly involved in the day-to-day operation of the Encyclopedia was Penny Motley, who efficiently functioned as project secretary during the planning phase. During the main phases of the project, it was Yvonne Bennett who was responsible for secretarial and organizational matters. She deserves much applause for her superb and efficient help in the day-to-day running of the editorial office, making sure that all manuscripts and proofs were processed quickly, and also for assisting with the organization of various meetings. Not least, Baltes thanks the administrative office of the Max Planck Institute, and there especially Nina Körner and Karin Marschlich, for their competent work in managing the project budget, as well as Sabine Norfolk who handled most of the numerous fax

transmissions with ever present smiles and friendliness. Finally, in the Berlin editorial office, thanks are also due to Susannah Goss for her excellent work in translating individual articles into English.

Individual section editors wish to thank the following scholars who gave them substantive advice in their work: Richard Abel, Itty Abraham, John Ambler, Karen Anderson, Mitchell Ash, Alan Baddeley, Boris Baltes, Manfred Bierwisch, Michael Bittman, Sophie Bowlby, John Carson, Shelly Chaiken, Roger Chartier, François Chazel, Stewart Clegg, Carol Colby, Philip Converse, James Curran, Jerry Davis, Natalie Z. Davis, Peter Dear, Juan Delius, Michael Dennis, Josh DeWind, Sherry Diamond, Elsa Dixler, Georg Elwert, Howard Erlanger, Drew Faust, Malcolm Feeley, Nancy Folbre, Michael Frese, Angela Friederici, Lawrence Friedman, Bryant Garth; Victor Ginsburgh; Marcial Godoy, Frances Goldscheider, Calvin Goldscheider, John H. Goldthorpe, Reginald Golledge, William Graziano, Stephen Gudeman, Mauro Guillen, Doug Guthrie, John Hagan, Eric Hershberg, Steve Heydemann, Stephen Hilgartner, Judith Howard, William Howell, Jill Jaeger, Bob Kagan, Joe Karaganis, Roger E. Kasperson, Ronald Kassimir, Robert W. Kates, Wolfgang Klein, Hans-Dieter Klingemann, Bert Kritzer, Kay Levine, Steven Lukes, Michael Lynch, Akin Mabogunje, Stuart Macaulay, Donald MacKenzie, David Magnusson, Michael McCann, Sally Merry, Peter Meusburger, Sieglinde Modell, John Monahan, Kevin Moore, Gerda Neyer, Hiroyuki Ninomiya, Jodi O'Brien, Eva Oesterberg, Mark Osiel, James L. Peacock, Susan Phillips, Trevor Pinch, Wolfgang Prinz, Sheri Ranis, Harry Reis, Estevao C. de Rezende Martins, Marc Richelle, Leila Rupp, Gigi Santow, Austin Sarat, Simon Schaffer, Linda Scott, Tim Shallice, Seteney Shami, Ronen Shamir, Susan Silbey, Wolf Singer, Sheila Slaughter, Gerhard Strube, Ursula M. Staudinger, J. Stengers, Stephen M. Stigler, Michael Stolleis, Mark Suchman, Denis Szabo, Verta Taylor, Ashley Timmer, David Trubek, Leslie Ungerleider, Don Van Arsdol, Jakob Vogel, Rita Vörg, Judy Wajcman, Mary Wegner, Wlodzimierz Wesolowski, Steve Wheatley, Björn Wittrock, and Vincent Wright (deceased).

Section editors also thanked the following persons for their research assistance: Pamela Anderson, Susan Augir, Anja Berkes, Chantale Bousquet, Aida Bilalbegović, John Clark, Susanne Dengler, Kathrine Derbyshire, Annie Devinant, Casey B.K. Dominguez, Barbara Dorney, Elizabeth Dowling, Tracey L. Dowdeswell, Carolyn Dymond, Debbie Fitch, Susannah Goss, Verhan Henderson, Andrew Hostetler, Gudrun Klein, Heike Kubisch, Angie Lam, Ellen Lee, Valerie Lenhart, Kay Levine, Allison Lynn, Helena Maravilla, Carol B. Marley, Marion Maruschak, Michael McClelland, Rhonda Moats, Birgit Möller, Katja Neumann, Linda Peterson, Justin Powell, Paul Price, Xandra Rarden, Chris Reiter, Deborah Sadowski, Heidi Schulze, Heidi Sestrich, Keith Smith, Judith Thompson, Karen Varilla, Stuart Vizard, Danelle Winship.

It is difficult to single out one person as especially helpful. Despite the risks involved, we would like to highlight one person (see also Introduction). As shown in the front matter, beginning in the second year of the planning phase, Julia Delius served as our scientific editorial assistant. For our internal process of editorial review and management, Julia Delius was the mastermind of editorial coordination. Her work was simply outstanding.

Finally, we express our thanks to several individuals at Elsevier publishers whose work was both essential and helpful to us throughout. Barbara Barrett started the ball rolling for the entire Encyclopedia project, and was a master at negotiating out the fundamental arrangements at the beginning. Geraldine Billingham, as executive editor, also played an important role in the development of the project, as well as carrying the heavy responsibility for ensuring that all the financial and operational aspects of the project were realized. She executed this work with directness, skill, and tact. Angela Greenwell coordinated the editorial process with dexterity, calmness, and good judgment. Three persons were responsible for monitoring the progress of entries from Elsevier's side: Michael Lax for a time at the beginning; Jayne Harrison, who carried an overwhelming load of manuscripts month after month, and Helen Collins, who was responsible for the equally demanding job of shepherding the manuscripts through the entire production process. Ruth Glynn skillfully and imaginatively masterminded the development of the electronic version within Science Direct. We know how much the success of the Encyclopedia has depended on these individuals and their staffs, and our appreciation and admiration is here recorded.

Our expressions of gratitude and respect for the authors, section editors, reviewers, counselors, and editorial team, however, are not meant to distract from our own responsibilities as editors in chief. Let us hasten to add, therefore, that those whom we acknowledge deserve most of the credit but little of the blame for whatever shortcomings remain.

Neil J. Smelser
Paul B. Baltes
Palo Alto and Berlin
June 2001

INTRODUCTION

Alan Sica's article in this encyclopedia observes, "The urge to systematize and rationalize both common and esoteric knowledge has been strongly and continuously in evidence for at least 2400 years in the West" (Sica, 2015). Sica dates the origins of this urge to Plato's nephew Speusippus, who took up the challenge of Plato's call for an *encyclopedia* (from Greek words meaning 'general education'), and traces the urge though Pliny the Elder, Vincent of Beauvois, Francis Bacon, Denis Diderot, and a great many others. Today, an encyclopedia is simply a self-contained reference work "with two aims: to include up-to-date knowledge about a particular discipline or group of disciplines and to make this knowledge conveniently accessible" (Smelser and Baltes, 2001). Such are the aspirations of the present work.

Histories of the concept of an encyclopedia are widely available and need not occupy us here. Those interested in where the *International Encyclopedia of the Social and Behavioral Sciences* (IESBS) fits into the long history of encyclopedias will do well to consult the Sica article quoted above or the Smelser—Baltes 'Introduction' to the first edition of this work.

This is the second edition (2/e) of the IESBS. Elsewhere, I acknowledge my immense debt to the editors of the first edition, Dr Neil Smelser and Dr Paul Baltes. Without their perspective and template to follow in assembling the second edition, this version would have scarcely been possible. The very thought of an encyclopedia covering *all* the social and behavioral sciences, one that drew on scholars from *all* corners of the globe, is itself so audacious that one would hesitate even to begin without a pretty detailed road map to the terrain.

On the occasion of the publication of Robert E.L. Faris's widely acclaimed *Handbook of Modern Sociology*, Joseph Gittler was moved to ask, "With the plethora of new handbooks, reviews, and compendia in sociology, one wonders whether there is a need for yet another one." That question was posed almost 50 years ago; the ensuing half-century has been marked, as Sica says, by "an avalanche of reference materials the likes of which had never been seen in libraries prior to about 2000." So readers and critics are within their rights to ask: Why a second edition? Why now?

The first edition (1/e) was reviewed in *Contemporary Psychology* as "the largest corpus of knowledge about the social and behavioral sciences in existence" (Park, 2004). According to readily available data sources, IESBS 1/e has been cited nearly 6000 times in subsequent scholarly literature and has an h-index ($h = 24$) that would be the envy of many full professors. Citations are only one measure of impact, of course, and probably not the most important measure for a basic reference work intended more for students and a general audience than for practicing professionals. In addition to the thousands of scholarly citations, items from IESBS 1/e were 'hit' almost two *million* times on Science Direct between online publication in November 2002 and August 2014 — two million instances where IESBS 1/e was likely consulted as a basic reference source, to get quickly up to speed in a new area of research or to provide background for a paper or project, or just to satisfy a reader's curiosity. The first edition, in short, emerged soon after publication as a go-to reference work throughout the social and behavioral sciences. Michael Shanahan referred to the first edition as "the atomic bomb of reference works." It was thus an easy conclusion that the work had sufficient value to keep it alive and current.

In reading selected articles from the first edition, however, I was taken aback by how much and how quickly they had aged. The first articles I looked at were those pertinent to my own areas of research and in nearly every case, there was important recent work that I felt needed to be discussed. With the assistance of colleagues in other areas of the social and behavioral sciences, it became obvious that this was a general problem. To be sure, much of the material in 1/e has enduring value; indeed, roughly half the articles in 2/e are updated and revised items from the first edition. Still, it is sobering to realize just how quickly the frontiers of social science

knowledge shift and thus how quickly a basic reference source becomes dated. I am certain there are articles in the current edition that are already in need of some updating.

Smelser and Baltes enumerated six criteria that guided their decisions about what to include and what to leave out. The criteria are as follows:

1. secure knowledge, realizing that security of knowledge is a dynamic and relative term,
2. knowledge with balance and comprehensiveness,
3. knowledge that is integrative rather than fragmented,
4. knowledge that places the evidence into historical and theoretical context,
5. knowledge that highlights connections between topics and fields, and
6. knowledge that combines, where possible, theory and practice.

I would like to say I have followed these same criteria in determining the content of 2/e, but all six criteria have proved problematic in one or another way and thus deserve some comment in light of the present work:

1. What is secure knowledge today is apt to be recognized as wrong tomorrow. Many of our requests for updates to 1/e articles generated some response to the effect, "All of this is completely obsolete. We need to write a new entry from scratch." One would expect this to be true of areas of research such as behavioral genetics, say, or cognitive neuroscience or other fast-moving scientific fields, but it also turns out to be true of archaeology, history, and philosophy. The leading edge of research in *every* discipline threatens received wisdom; those who content themselves with received wisdom ('secure knowledge') will quickly find themselves behind the times. So our charge to authors was to focus less on the 'secure knowledge' in their respective fields and more on the cutting edge — the new perspectives, methods, findings, and issues that will animate social and behavioral science research in the coming decade.
2. Throughout the social sciences, the distinction between theory and ideology is sometimes difficult to discern, and so too the distinction between applied research and community or political activism. We need not invoke Max Weber's conclusions about the impossibility of a truly value-free social science to understand that ideological undertones and political preferences can often be detected in social science research work; sometimes, they are quite explicit. Nor is it much of a surprise to learn that many social scientists struggle, not always successfully, to distinguish between what they want the world to be and what the world in fact is. Such struggles are part of the process by which knowledge develops and are thus in evidence in many of the 2/e articles. It would be unwise to enforce by editorial fiat a consensus on issues that the social sciences themselves have yet to resolve.
3. The fragmentation of knowledge *across* disciplines is far more serious that the fragmentation of knowledge *within* them, although the latter is a problem as well. Many well-informed sociologists, for example, take pride in reading widely and can speak with some authority about what is going on in the field, even in areas of sociology that do not directly concern them. I assume this is also true of the other social and behavioral science disciplines and areas. But rare is the sociologist who is cognizant of work being done, say, in social geography *even when*, as is often the case, the fundamental problems, theoretical issues, and methodological approaches are similar. This is a widespread problem across the disciplines: The evolutionary psychologists do not know as much as they should about what the anthropologists are doing; the economists ignore a lot of pertinent work in sociology and political science; etc. For better or worse, disciplinary differentiation is an inherent element in the process of knowledge development and discovery, so this is a reality to be faced, not a problem to be solved. We dealt with this reality mainly in two ways: (1) Authors were encouraged wherever possible to think across rather than strictly within their disciplines. (2) Calling relevant work done in other disciplines to the reader's attention was a guiding principle for the choice of cross-references for each article.
4. Social-constructionist theories of knowledge would argue that knowledge does not become knowledge until it is placed in historical, cultural, social, political, and theoretical context. As put very simply and succinctly in the opening line of the famous text by Berger and Luckmann, "reality is socially constructed" (1966: 1). This is no less true of social science knowledge than knowledge in any other realm. Unfortunately, a great deal of what we think of as social science knowledge is based on biased samples of WEIRD people — that is, Western, Educated, Industrialized, Rich, and Democratic (Henrich et al., 2010). (The same point has, of course, been made by many others.) The WEIRD, thus defined, represent a rather exotic minority group judged by world standards, and the challenge for IESBS 2/e was therefore twofold: (1) to recruit non-WEIRD editors and authors where possible; and (2) to persuade all authors to incorporate comparative, cross-cultural, and

international themes and perspectives wherever it was possible to do so. This effort was more effective in some sections than in others. Moving away from nation-specific literature, themes, and results to a truly *international* (the I in IESBS) account of the social and behavioral sciences was an ever-present *desideratum* in my discussions with editors and authors.

Alas, an emphasis on cross-culturalism often brings to light that everything, or nearly everything, seems to vary by culture, subgroup, ethnicity or nation, and at that point the question arises whether social science generalization is even possible. Are there universals that cross all social groupings? Or does social science dissolve into a mist of group-specific particularities that adduce no general principles? That hardly seems desirable. Yet myopic and ethnocentric fixations on one's own society or culture are scarcely to be encouraged either.

The worst offenders in this regard tend to be social scientists from the USA (and from the West more generally), who, of course, also comprise the largest share of editors and authors for IESBS 2/e. True, as with greenhouse gases, the USA (and the West) also produce the largest share of the world's science, social and otherwise, and so it is inevitable that they also represent the largest share of IESBS 2/e contributors. The Swedish social anthropologist Ulf Hannerz wrote about this very issue in his marvelous essay, "Editing Anthropology" (Hannerz, 2010). Hannerz quotes a Canadian anthropologist who said of the "neighborly presence" of US anthropology that it was like being "in bed with the elephant." The same is true of most or all of the disciplines covered in this work. But then in a passage remarkable for both its insight and its generosity, Hannerz remarks, "No doubt tensions and conflicts may arise out of this situation, but perhaps it is better to understand that the elephant cannot help being an elephant, and that it makes sense for it, in its habitat, to behave in elephantine ways. A well-trained elephant, too, can do a lot of good, such as in carrying heavy loads." So if the elephant that is Western social and behavioral science has been pressed to carry the heavier load in these pages, that is, the price to be paid for being an elephant in the first place.

The larger issue here is that the social and behavioral sciences, which were largely birthed in the West, in Europe and the United States, mainly address a trans-Atlantic scientific dialogue, a dialogue that is carried out almost exclusively in English. Indeed, throughout much of the world, a scientist's stature is indexed in part by his or her success in publishing in English. Publications in the native language are simply *assumed* to be inferior. The main exceptions, tellingly, are French and German social scientists whose native-language publications are valorized. A Dutch or Portuguese or Hungarian social scientist who only published in the native language would be seriously punished in merit and tenure reviews. Elsevier's citation database Scopus *requires* English-language abstracts before a journal will even be considered for inclusion. And English (with American spellings) is likewise the official language of this encyclopedia. No resources were made available to get articles submitted in other languages translated (although several such articles were submitted). Inevitably, this biases the encyclopedia's coverage in favor of social science addressed to the trans-Atlantic dialogue. Consequently, a great deal of excellent social science published in Spanish, or Mandarin, or Farsi, or any of the other world languages, is overlooked.

That said, steps were taken to improve the internationalism of the encyclopedia's coverage throughout the 4 years of its development. To begin, I sought area and section editors from around the globe and urged them whenever possible to seek international (vs strictly Western) authors. Articles were often returned to their authors with explicit instructions to add international coverage. And when all efforts failed and we ended up with articles that were unmistakably restricted to a single nation in their coverage (frequently but not always, this was the US), I indicated the national focus in the article subtitle. Still, a great deal more WEIRD social and behavioral science remains in these pages than would be desirable in an *international* encyclopedia. In a later section, I give the national breakdown of everyone involved in this project.

5. An encyclopedia that "highlights connections between topics and fields" is easier to envision than to accomplish. Criterion (3) above speaks to the disciplinary fragmentation of our social science knowledge. William Easterly, the NYU economist, has written about the 'tyranny of experts' but the tyranny of the disciplines is an equal problem, a tyranny sanctified by the very academic structure of the modern university, where the separate and often warring colleges are each comprised of assorted departments, the latter representing basic academic disciplines. Interdisciplinary programs are almost invariably relegated to various centers, institutes, or specialized research laboratories — in short, to the periphery of the university's power structure. And while everyone *says* they want to encourage multi- and interdisciplinarity, very little is done to make that happen. Instead, departments remain as the fundamental unit of academic organization.

   Hortatory admonitions to editors and authors have made IESBS 2/e somewhat more interdisciplinary than its several predecessors, but in the end, the disciplinary emphasis in many of our articles would be hard

to overlook. Still, there are many sections of the work that were clearly developed with interdisciplinarity in mind and in which one finds interdisciplinary social science at its current best: environmental and ecological sciences; health; life course; sexuality; GLBT studies; public policy; evolutionary sciences; war, peace, violence, and conflict; and genetics, behavior, history, and society are a few sections that come immediately to mind.

I am particularly pleased with the extensive coverage given in 2/e to the interactions between the biological and social sciences. Harry Whitaker once remarked in a private e-mail that "we are all witnesses to the marriage of biology and the social sciences." Many of the articles found here are offspring of that marriage. And those articles leave little doubt that the future offspring of this marriage will be among the most exciting and insightful social science products of the coming decade.

The social sciences once resisted everything biological as rank reductionism; in addition, the social scientists have always feared that a mature and complete biology would eventually drive us out of business. Articles included in IESBS 2/e make it clear that 'nature' versus 'nurture' was the wrong question from the very beginning, that what we need to understand is how biological inheritance and social and cultural forces *interact* to produce individual and collective outcomes. This is where a lot of the interesting action in the social sciences is going to be in the coming years.

6. The coverage of the practical or applied sides of the various disciplines has been increased in this edition, so the applied content of 2/e certainly exceeds that of its predecessor. New to this edition is the entire section on applied social and behavioral sciences; also new is our large section on social work and the separate section on applied, industrial and organizational psychology. But as Sara Strickhouser and I say in our article on the history of applied social research, "The history of 'applied social science' is indeed the history of the social sciences themselves" (Strickhouser and Wright, 2015). All of the social sciences in their modern form were birthed in the post-Enlightenment effort to understand why people, their institutions and society as a whole were as they were — why greed was more visible than generosity, why oppression was more common than freedom, why inequalities of various sorts characterized every social institution. To the founders of the disciplines, the modern distinction between basic and applied scientific concerns would have seemed meaningless, as indeed it was.

The Planning Phase and Editorial Structure

Elsevier's original acquisitions editor for this project, Scott Bentley, discussed the broad outlines of our attack on IESBS 2/e with me in a series of phone calls in the early months of 2010. By May 2010, certain of these outlines had come into sharp relief. There would be a single editor in chief with a tier of 'responsible lieutenants' to assist. These lieutenants started out as advisory editors but soon morphed into the 10 area editors in the final editorial structure. Each area editor would in turn oversee various sections and each section would have its own editor or editors. The original plan was that the area editors would each be responsible for approximately 400 articles and each section editor responsible for about 100 articles, so that no one would have an excessive amount of work compared to everyone else. In the end, however, some sections required more articles and others fewer, so the areas vary from fewer than 300 to more than 600 articles, and the sections vary from fewer than 30 articles to well more than 200.

Prior to my first discussions with Scott Bentley, Elsevier had commissioned about 20 'market surveys,' roughly half from professional librarians and the other half from academics, each focused on 'what was right and what was wrong' with the first edition. The most insistent demand that surfaced was for a fully electronic, computer-searchable work either in addition to or instead of a print version. In the end, both an e-version and a print version are being made available. But there were also consistent concerns expressed about spotty coverage of some areas: no coverage of social work to speak of; inadequate coverage of accounting, marketing, and business; no separate section of criminology; haphazard coverage of applied topics and concerns; and so on. And there were the predictable concerns about undue Western domination of the work.

Working from the 1/e Table of Contents and this stack of 20 surveys, I tinkered for a few months with how best to expand coverage to address the concerns our reviewers had expressed; the result was (more or less) the editorial structure shown elsewhere in the front matter of this work. Thus, the 53 sections of 2/e are basically the 39 sections of the first edition plus sections that were added to cover important emerging areas of research interest (e.g., gay, lesbian, bisexual, and transsexual studies) or to provide deeper coverage of disciplines and subdisciplines that the first edition treated lightly if at all (applied social and behavioral sciences, social work). A

few of the first edition sections were eliminated entirely: specifically, integrative concepts and issues (something of a catch-all category for 1/e articles that were highly interdisciplinary or simply did not fit anywhere else) and gender studies (gender is now so thoroughly integrated into the research and thinking of all the social and behavioral science disciplines and subdisciplines that a separate section was unnecessary and somewhat retrograde). Others were altered or expanded in significant ways (organizational and management studies, for example, became the second edition section on management, organizations, business, marketing and finance; expressive forms evolved into the 2/e section on culture and the arts; linguistics was subdivided into three separate sections; etc.) And some subdisciplinary areas that were part of other sections in the first edition were given their own sections in the second (life course studies; sexuality; criminology; labor studies; and war, peace, violence, and conflict are the most prominent examples), just to ensure adequate coverage.

The Introduction to 1/e (Smelser and Baltes, 2001) discusses at great length the intellectual architecture of the first edition and its evolution; the agonizing decisions about rules for the biographical articles; whether to organize the work by discipline, by concept, by an a priori taxonomy of social science knowledge, or in some other manner; and related structural matters. What resulted in 1/e was something of a hybrid model with some sections clearly representing specific disciplines, others representing 'overarching topics,' still others representing 'intersecting fields,' and so on. My task was far less challenging: I thought the architecture of the first edition served its purposes admirably and so I adopted it wholesale for the second edition, with the small modifications noted above.

While each of the 53 sections of 2/e has some more or less obvious justifying logic or substantive or disciplinary coherence, their arrangement into the 10 areas of the second edition does not. As already indicated, decisions about what sections to include and exclude were made very early in the development of the second edition, based on what was in the first edition, what Elsevier's marketing surveys suggested as significant lacunae, and my own sense of things. The arrangement of the sections into areas came later and was dictated largely by the interests and expertise of those who had been persuaded to sign onto the enterprise. Thus, all the Linguistics sections are in Area Five along with the cognitive and neuroscience sections because Harry Whitaker at Northern Michigan University had been a linguist first, a neuroscientist second, and a historian of psychology third. Likewise, Area Eight contains its seemingly chaotic hodgepodge of evolutionary sciences, genetics, religious studies, science and technology studies, and law because these happen to be the fields of interest of the redoubtable Barbara Prainsack of King's College, London, whose editorial talents are as deep as her interests are broad. Simplifying only slightly, section editors were chosen for their substantive expertise in particular areas of research (as well as their international or cultural 'range'); the plan was that section editors would review each of their articles for completeness of coverage, currency, fairness, and the like. In contrast, area editors were chosen for their breadth of interest and knowledge spanning multiple sections – people who by nature, experience, and training would be good at seeing the big picture. The role of the area editors was to assure that the articles were at least modestly international and interdisciplinary and formed some sort of coherent whole.

As laid out in an early e-mail to one of the area editors, "In my mind, Advisory [Area] Editors are generalists and Section Editors are content specialists. The Section Editors need to bring breadth of knowledge to their responsibilities, of course, but the primary job requirement is expert understanding of the particular field or section. We need section editors who can commission pieces that adequately review past developments in the subject area, but who can also shape their portfolios to identify major unanswered questions and new research developments." This was the general model followed throughout the recruitment process.

The approach just sketched inevitably left a residual area made of up sections that none of the other area editors were willing or able to claim. That proved to be Area Ten. A very large number of scholars from various disciplines and world regions were approached about serving as the Area Ten Editor. All demurred until I approached Martin Bulmer of the University of Surrey, who served the project for about a year but was unable to continue and subsequently left the Board. So for the final year of the project, the editing of Area Ten was done mainly by me.

The online subject classification for IESBS 1/e did not correspond precisely to the sections of the first edition; the subject classifications listed articles by broad general topic regardless of which 1/e section developed them. So for the first year or so, my assistants and I labored to assign every 1/e topic to one of the 53 2/e sections. With 53 sections to populate with articles and about 4000 articles to classify, the process of assigning articles to unique sections occupied huge amounts of time and generated endlessly complicated spreadsheets. (After about a year of this, a document surfaced in the Elsevier archives that showed exactly where each 1/e article had originated.)

Along with populating the 2/e sections with articles, searching for area and section editors occupied a major part of the early going. The original idea was to identify the 10 area editors first and then enlist them in the

search for their section editors, but in fact, these processes were simultaneous and were about half-completed when the two planning meetings were held: the first in San Diego on 19 and 20 May 2011; the second in London on 5–7 June 2011. Although not part of the plan, the first meeting was mostly attended by area editors and the second, by section editors.

The agenda for both meetings was largely identical: achieve clarity on the respective roles of the various editors; solicit advice on filling the unfilled editorial slots; get buy-in on the project *mantra* (internationalism, interdisciplinarity, inclusiveness!); explain the relationship between the first and second editions (e.g., that all 1/e authors would be offered the opportunity to update their articles); explain the process of assigning articles to sections; and the like. In almost all cases, consensus was quickly forthcoming.

The largest substantive change in the second edition is the treatment of psychology. (Whether measured by students, practitioners, professors or programs, psychology is the largest of the social and behavioral sciences.) In the first edition, the whole of psychology was contained within four large sections: clinical and applied psychology; developmental, social, personality, and motivational psychology; cognitive psychology and cognitive science; and behavioral and cognitive neuroscience. Cognitive science and neuroscience are, of course, rapidly growing sectors of the psychological discipline and it seemed appropriate to devote an entire area of the second edition to them. This area contained seven separate sections (three of them devoted to linguistics). And the 'softer' psychological sciences were placed in a separate area comprised of eight sections (including psychiatry and social work). These changes were made to assure that 2/e had adequate coverage of the entire psychological enterprise (a concern that was raised in some of the reviews of 1/e).

The structure of the editorial team was developed to serve two purposes: first, to divide up the labor into manageable parts; and secondly, to assure that every article in the final product would be reviewed by at least three scholars: the respective section editor, area editor, and the editor in chief. Since we were all aware of one another's identities throughout, the review process was not blinded, but every article in this work has been thoroughly peer-reviewed and vetted. In many cases, these articles have been through four, five, six, or even more revisions before being accepted for inclusion in the work.

Recruiting Editors and Authors

IESBS 2/e faced two different recruiting tasks: recruiting editors and recruiting authors. As indicated elsewhere, the original plan was that I would recruit area editors largely from my own personal networks and they in turn would recruit their section editors. In practice, the process was much more convoluted. First off, many of my 'first choice' candidates were hesitant to involve themselves in such a daunting and ambitious project. In some cases, an initial agreement to come aboard was followed a few weeks or months later by withdrawal as the true scope of work came into sharper focus. Some people that I tried to recruit as area editors demurred but agreed to serve as section editors; in other cases, candidates for area editors were nominated by section editors. In a couple of cases, there was a complete team of section editors prior to the successful recruitment of a corresponding area editor. And so on. The process of assembling an editorial team for the project was by no means linear.

Personal networks – mine and those of the people I persuaded to sign on – were the largest single source of ideas for other editors, by far. But personal networks tend to follow disciplinary and national lines and become rather quickly exhausted. In selecting both editors and authors, it was of course essential that all relevant perspectives be covered and that the breadth of fields was adequately represented. So other sources of ideas were tapped: the expertise of the Major Reference Works team at Elsevier; editorial boards of leading journals in the respective fields; Google Scholar citation counts; the knowledge and networks of people who had been involved in preparing the first edition – basically, anywhere names of top scholars in particular areas could be located. I did not keep systematic track of the number of people approached, much less of the outcomes; but in reviewing my e-mail archives from the early period of the project, I probably asked (on average) somewhere between six and eight prospects before I found someone to agree (an average that was highly variable across the areas and sections).

In the initial plan, area editors would recruit their own section editors and the section editors would in turn recruit their own authors, but the reality was again different. Inevitably, my negotiations with prospective editors (both types) would often result in a declination of the editorial role but an offer to write an article on a particular topic (or topics), offers I readily accepted. So in some cases, I had committed authors of particular articles well before I had the corresponding section or area editor in place. And many of the section editors likewise leaned on their area editors and on me for author suggestions, contacts, and outreach. So all the editors

were involved in locating willing authors (and not coincidentally, in making suggestions for articles to be included in the final work).

No one was asked to keep precise statistics on how many authors were sought before an agreeable author was found. My sense is that the 2/e editors had a somewhat tougher time with this than the 1/e editors had (but on the other hand, the 2/e editors had all the 1/e authors to work with, which Smelser and Baltes certainly did not have). The 1/e editors report that about 60% of those invited to write articles agreed to do so on the first 'ask' (with equivalent success rates in each subsequent 'ask'). In 2/e (or so I would guess), the success rate was probably closer to 50% and possibly even lower. They also report that something in excess of 90% of those who agreed to write for 1/e in fact contributed "acceptable entries in time to be included…" In the 2/e case, we found ourselves still soliciting authors within a few weeks of the submission deadline and some dozens of authors pulled out of the project at the last minute. Still, when all the dust settled, there were just about 800 articles planned for both editions that never materialized and both editions ended up with just fewer than 4000 articles. Perhaps these are 'natural limits' for a work of this sort.

Biographies*

In the Introduction to 1/e, Smelser and Baltes provided a short history of and rationale for the decision to include a limited number of biographical articles (150 of them, to be exact). This was evidently a controversial and contested decision since some of those associated with 1/e felt that biographical articles had no place in an encyclopedia focused on substantive knowledge (versus the personalities of those who produced it). As Newton said (paraphrasing a passage from Bernard of Chartres), "If I have seen further, it is by standing on the shoulders of giants" (a passage made famous among social scientists by Robert K. Merton's *On the Shoulders of Giants* (1965)). In other words, discovery is only possible because its discoverer is able to refer to knowledge already gathered and accumulated by his or her predecessors; and since all discoveries – small and large, substantial and minor – contribute to the production and accumulation of knowledge, singling out particular scholars for special attention would be both pointless and invidious.

This position, although understandable, was abandoned in the first edition and remains so in the second, largely because it is not possible to understand the social sciences without knowing the individuals who contributed to it. C. Wright Mills once defined the sociological imagination as the intersection of biography and history (Mills, 1959). To know the social sciences therefore requires biographical and historical knowledge. The social sciences are distinguished from the physical and biological sciences in the way they produce knowledge because individual human beings, including social scientists, invest meaning in their actions. Only through understanding the meaning that individuals give to their actions are social scientists able to provide explanations of human behavior and its outcomes. And what applies to social action in general applies to the production of social science knowledge as well. It thus makes sense to include biographical accounts of social science personages who have been particularly distinguished in making sense of human action and have in turn made major contributions to social science knowledge. To acknowledge individual social scientists with biographical articles is also to acknowledge their special and particular insights.

Once the decision was made to include biographies in 1/e, the next major decision was whom to include and whom to leave out. Two arbitrary but defensible principles governed these decisions: (1) the total number of biographies was not to exceed 150 (chosen because it seemed like a manageable number) and (2) only biographies of the dead would be included. The 1/e section editor for biographies, Karl Ulrich Mayer, consulted handbooks and encyclopedias, asked other section editors to name and rank the most important names in their respective disciplines, ran citation checks, and finally submitted a consolidated list to various experts for review. This resulted in some additions and some deletions and in the end 147 biographies made it into the first edition.

Instructions to authors writing these biographies directed them to include "a brief sketch of the major dates and events in the life of the biographee," to describe "the major contours of the [person's] substantive contribution," and to highlight the "importance and relevance of the biographee's work for the social and behavioral sciences." Largely the same instructions were given to 2/e biographers.

The selection criteria for 2/e were very different. First, on the reasoning that well-done biographies of leading figures is one of the things that draw readers to a work such as this, the total number of biographies was

* My thanks to Andreas Hess for drafting this section of the Introduction.

increased by more than 100 (to just over 250). In a major departure from 1/e, much of the increase is made up of biographies of the living. The 1/e restriction that excluded living persons resulted in anomalies that we thought needed to be addressed. As life expectancy has expanded in the twentieth and twenty-first centuries, so have the life spans of social scientists. Claude Levi-Strauss, to cite one obvious example, lived to the age of 101 years. When 1/e was published, he was in his 90s, was widely cited, was recognized universally as a modern classic, indeed a genius, of social anthropology – and yet, owing simply to his longevity, he was not included in the 1/e biographies. Biographies of, for example, the economist Herbert Simon, the political economist Albert O. Hirschman, the sociologist and philosopher Jürgen Habermas, and the linguist Noam Chomsky were all excluded for the same reason; indeed, Habermas and Chomsky still live as this is being written (Fall, 2014). In all these cases, the major works had been produced decades earlier, their major imprints on the social and behavioral sciences were already evident, their eventual inclusion in works such as this was inevitable. Are readers to be deprived of accounts of their lives, times, and contributions just because they have survived into deep old age?

Once the decision was made to include biographies of the living, however, it was not always easy to decide who among the living merited inclusion. Often the editors had to make decisions on a case-by-case basis, frequently in extended consultation with colleagues or experts in the field. Criteria used to make these decisions were whether the potential biographee had a reputation beyond one culture, nation, or language group; whether there was a record of sustained production over several decades; and whether there was an impact beyond the confines of a single discipline. These criteria reduced our list of suggested biographees considerably. Early lists of candidates numbered as many as 200 new names (in addition to the 147 biographies included in 1/e). In the end, as noted earlier, somewhat more than 100 new names were added.

In a few cases, persons were included that arguably did not satisfy our inclusion criteria. One such is Raul Hilberg, who became famous mainly for having written one very important book, *The Destruction of the European Jews* (1961). Hilberg's book is still regarded as the seminal work in Holocaust studies, a field of research that came to prominence much later; we felt that his signal contributions to Holocaust studies merited a biographical article. Much the same could be said, perhaps, of André Gorz, a well-known social theorist from France, and Albert Memmi, whose work is on colonialism, anticolonialism, and racism. These and other examples could and probably will raise questions about the porousness of our criteria. Whether we were right in giving 'trespassers' their space is open to debate. In any case, whether Hilberg, Gorz, Memmi, and others do or do not merit their biographies is for readers, not us, to decide.

Other important changes in the 2/e biographies section include, first, a conscious effort to attain a better gender balance, including more women both as biographees and as authors; and second, expanding the biographies both geographically and culturally. In the end we made some inroads in both respects but fell short of our internal goals. One of the main reasons for this is that any encyclopedia must, in the first instance, be true to the disciplines it represents. This means being true to the real status of important players, their networks and disciplinary power relations, and their academic capital in their respective fields and beyond. Change in these respects has been noticeable; certainly, the growth of the social sciences in Asia has been remarkable; and in most disciplines, the proportional presence of women has increased. But modest change in the right direction does not a revolution make. Too many nonwhite, non-Western, and nonmale practitioners are still being left out on the disciplinary peripheries and are not fully represented – not in their home disciplines and not in our encyclopedia either.

We state this fact with regret. In many cases, the limiting factor is not excellence but simple visibility. Being part of the trans-Atlantic social science dialogue and engaging this dialog mainly in English translates into more visibility, as discussed earlier. This gets a scholar on the radar screen. Equally excellent work engaging other intellectual dialogues in languages other than English does not. A great many outstanding scholars have thus gone unrecognized in 2/e for precisely this reason. That being said, strenuous efforts were made to make the 2/e biographies more inclusive. Among those included are the Argentinean educationalist Sarmiento, the Brazilian sociologist Cardoso, and the Japanese political scientist Maruyama, to name just a few. This is, however, 'just a few' of the many dozens of prominent social and behavioral scientists 'out there' whom we would have included had we been given more time and more resources (to get non-English works translated, for example). We do feel that we have made some important inroads and beg the reader's understanding of the limits within which we worked. We can only hope that the next edition will strive for more inclusiveness and better representation than we were able to achieve.

Another entirely new feature in the 2/e biographies is the series of 'collective biographies.' In many instances, the intellectual lives of individuals who work in research groups intersect and form a network that makes the

entire group (or paradigm) successful. Examples include articles on the Durkheimians, the Annales School, the Frankfurt School, and several others.

As indicated earlier, instructions to authors were changed little from 1/e. All authors were asked (1) to include the most important biographical facts (country of origin, generation, education, influences, other formative experiences, networks, etc.); (2) to list the most important output (discoveries, publications, etc.) and to briefly discuss the subject matter and content of the most important publications or discoveries; (3) to look at the lasting impact of the person and his or her work (if possible, beyond just one discipline, language group, or culture); and (4) to provide a bibliography of primary and secondary sources related to the biographee and his or her work. Most authors stuck to these guidelines.

Finally, we state for the record that there are a number of important social and behavioral scientists that we would have liked to include but for whom we were unable to find a proper biographer. The search for biographers went on for nearly 4 years. In many cases, our first-choice author agreed at once, but in other cases, we approached four, five, or even more people before an agreeable author was found. And in about two dozen cases, no such author was ever found, with the result that a deserving person's biography had to be dropped. Forgoing a case-by-case discussion of these deletions, let it be simply noted that this is why we have not included biographies of people such as Amartya Sen, the economist and social philosopher; Raymond Boudon, the French sociologist; Ronald Dworkin, the legal theorist; Avishai Margalit, the philosopher; or a collective article for the British Marxist historians (Eric Hobsbawm, E.P. Thompson, Christopher Hill, and Perry Anderson). Perhaps our most regrettable omission is Neil Smelser himself, for whom no biographer could be found despite at least a dozen attempts. (Paul Baltes's biography is included.) Neil is one of the giants on whose shoulders we all stand.

Redundancy

I mentioned earlier that in the beginning of the project, there was no 'map' linking each of the 1/e articles to its respective 1/e Section. Our efforts to create such a map invariably bogged down every time we hit an article that could plausibly belong to any of several sections, which was often. Obviously, it would have been possible to force every article into a 2/e section, but at the time it seemed advisable to involve the editors themselves in these decisions. So on numerous occasions, I distributed lists of 'orphaned' articles (articles for which no home had yet been designated) to the area and section editors, asking for foster parents to volunteer. Eventually, of course, every article found a home, but at a relatively late date in the process, I became aware that a few dozen articles had found more than one home. That is, some of the editors adopted articles without filing the appropriate paperwork with the editor in chief! In such cases, the result was two articles on the 'same' topic. (The 2/e Table of Contents was scoured multiple times looking for precisely these kinds of duplications but in the end, several proved elusive.)

In the large majority of cases, the content of the 'duplicate' articles was sufficiently distinct that both articles were retained, often with some retitling to help readers differentiate between them. For example, readers will find two articles on 'social identity.' One was recruited for the section on social psychology; the other for the sociology section. With rare exception, the two articles discuss different aspects of social identity from entirely different disciplinary angles; indeed, the two articles share only a small handful of common references. So it was an easy decision to retain them both: one appears here as Social Identity in Social Psychology; the other as Social Identity in Sociology. Careful readers will find perhaps a score of similar cases in the encyclopedia.

Alas, in a few regrettable cases, the overlap between duplicate articles was so pronounced that one of the articles had to be deleted. Since by the time these problems surfaced the articles had (often) been written and rewritten several times and had been accepted by both the section and area editors, the last-minute decision to delete a redundant article was painful. My sincere apologies to the authors involved.

Some redundancy in a work of this scope and aspiration is not only inevitable, it is probably also desirable. A reader interested in, say, social inequality will (one hopes) want to know what the sociologists, anthropologists, economists, and geographers all have to say about that topic. And if a few of the many articles on the topic say more or less the same thing, then what harm is done? Editors at all levels were asked to be alert to redundancies across articles and the editorial record shows that many were. That being said, quite a bit of topical redundancy no doubt remains, and that is not (in general) a matter of concern. It is what Smelser and Baltes refer to as the "inevitable residue of overlapping."

The Review Process

Once the table of contents had stabilized, each of the editors was asked to review the 1/e articles assigned to their section or area and come to various decisions. In some cases, 1/e articles could be reprinted more or less 'as is,' with perhaps some updating of references for readers seeking entry points into the current literature. This was especially the case with what were eventually designated as 'legacy articles,' e.g., Gabriel Almond's article on Civic Culture, James Gregor's article on Dictatorship, &c. In other cases, the 1/e articles needed some updating to be suitable for 2/e, either by their original authors when available or by others recruited specifically for the purpose. The general rule was that all 1/e authors would be offered the opportunity to do the updates themselves, and that other authors would be sought in the event of the original authors' declinations. In still other cases, the 1/e article was so obsolete than an entirely new article would be required. And then finally, the review of 1/e articles often revealed areas of current research that were inadequately covered; in these cases too, completely new articles would be sought.

Where appropriate, the relationship between the 1/e and 2/e versions of an article is spelled out in the article tagline. In many cases, there were issues of authorship to resolve — a 1/e article written by *X* and completely revised by *Y* is *Y*'s article although *X* might be identified in the tagline; but what of an article written by *X*, now deceased, and only modestly revised and updated by *Y*? Every decision rule that I formulated to resolve such issues soon confronted an exceptional case where the rule did not seem to apply. So in the end, the only workable rule was that everyone should get proper credit for their intellectual property, whether prime author or reviser, whether living or dead. If exceptions to this rule have crept into the final product (as they almost certainly have), I offer my apologies to those whose work has been slighted or improperly recognized. Deciding on proper authorship for many of our articles was a far more involved and difficult task than expected.

The section editors formed the first line of editorial defense and were the ones to whom article drafts were originally submitted. The section editors read and commented upon the draft articles and returned them to authors for revision. It is a rare article that appears here in its original form: on average, articles were revised two or three times before being sent to the area editors and subsequently on to me; in many cases, it was more like five or six revisions, with subsequent revisions at the request of the area editors and the editor in chief. And in some cases, articles were submitted to outside readers for independent review. As I stated earlier, the reviewing process was not blind, but it was quite thorough, as is reflected in the exceptional quality of the final product.

Internationalism and Inclusivity

A truly *International* Encyclopedia of the Social and Behavioral Sciences would of course require a global network of editors and authors *and* a commitment to internationalize the content of the work wherever possible. With respect to the editorial team for 2/e, this was definitely realized. The section editors and editors in chief who produced the first edition were drawn from only nine countries: The United States, Germany, Italy, Canada, Sweden, Australia, France, Switzerland, and the UK. Two-thirds of those editors were from the USA and only 13% were women. Area and section editors for 2/e represent 21 countries, US scholars make up only 38% of the total, and women comprise 36%. Thus, the proportional representation of women among the editors was nearly tripled in 2/e over 1/e while the predominance of the USA was halved. Nations represented among the editors of 2/e that were not represented in 1/e include Luxembourg, Greece, Finland, Japan, China, Ireland, Singapore, Spain, Russia, Austria, Israel, and the Netherlands. The presence of several Asian nations on this list is particularly gratifying. To be sure, the North Americans and Western Europeans still predominate, but they no longer monopolize the field.

Adding the International Board of Consulting Editors (see the following statement of Acknowledgments) increases the internationalism of the editorial team even further. Of the 45 members of that Board, only 12 (27%) are US social and behavioral scientists. Countries represented on that Board that are not otherwise part of the editorial team include three Central and South American nations (Venezuela, Argentina, Costa Rica), several Asian nations (the Philippines, Malaysia, South Korea, India), a few Western European nations (Norway, Denmark), two representatives from Central and Eastern Europe (Hungary, Croatia), two from the Middle East (Lebanon, Qatar), and one from South Africa. These editions bring to 35 the total number of countries with representation on the IESBS editorial team.

Much the same can be said of the 2/e authors, who are also more international than the 1/e authors had been. Smelser and Baltes noted in their Introduction that while authors from 51 nations were represented in the work,

58% of the authors were from North America and another 35% were from (mainly Western) Europe. "As to gender composition, 21% of the [1/e] authors were women." In 2/e, the proportion of women among the authors has increased slightly to approximately 25% and the percentage of North American authors has declined to fewer than half. Again, North America and Western Europe still contribute the larger share of the 2/e authors but the growing representation of social and behavioral science authors outside the West is both noteworthy and encouraging.

Another important point is that the international scope of the project is much more pronounced than editors' and authors' current affiliations would lead one to conclude. (This would have been equally true in 1/e as well.) Consider, for example, Michiru Nagatsu, author of our article 03053 on the history of behavioral economics. Dr Nagatsu was born in Japan and retains Japanese citizenship but was educated at Exeter and the London School of Economics and Political Science and wrote his IESBS 2/e article while on a postdoctoral fellowship in Finland. Or Guillermina Jasso, area editor for Area Three. Jasso was born in the USA, received her PhD from Johns Hopkins, and is on the faculty at New York University. By any standard, she would count as a US sociologist in our compilations. Yet her parents were Mexican of Basque, Spanish, Portuguese, and Dutch origins; Spanish is her native language; over the course of her distinguished career, she has published with coauthors from Germany, India, Israel, Mexico, the Netherlands, and Sweden; and she holds a permanent research fellowship at IZA, the Institute for the Study of Labor, in Bonn, Germany. Scoring her as 'USA' scarcely does justice to her biography or to the international perspective she brought to the editorial task.

What is true of author Nagatsu and editor Jasso is true in degrees of virtually the entire roster of IESBS participants. If one includes place of birth, citizenship, where educated, sites of research, visiting appointments, sites of fellowships, honorary professorships, invited lectures, and on through the list of highlights in a modern academic career, it is safe to say that every nook and cranny of the globe (save, possibly, Antarctica) is represented somewhere in the biographies of IESBS authors and editors. The true measure of internationalism, in short, is not so much where people come from or where they currently are, but rather the extent to which they bring a sensitivity and commitment to cultural and national differences into their work. Whether this was or was not realized in 2/e is for readers to decide.

Concluding Observations

Smelser and Baltes aspired in the first edition of this work to "assemble the whole range of knowledge – vast and complex as it is – of the social and behavioral sciences in one place." Since what does and does not qualify as 'social and behavioral science' is itself contested, it is not surprising that nearly every one of the market reviews commissioned by Elsevier to guide the development of the current edition noted content omissions in 1/e that reduced its usefulness and that needed to be addressed in a second edition. Critics can and no doubt will say the same about 2/e. I have already mentioned the nearly 800 articles that appeared on the 2/e Table of Contents at one time or another but that will not be found in the final product, either because agreeable authors could not be located or (less often) because agreeable authors never produced an acceptable article. And it is pretty easy to identify whole chunks of present-day social and behavioral science that are given short shrift, or no shrift at all, in this work – not because these chunks were judged to be unimportant but because limits of time, space, resources, and networks meant that some elements of the contemporary social science enterprise never came to our attention.

The social and behavioral sciences begin with what artificial intelligence guru Marvin Minsky once described as a "three pound computer made out of meat" – the human brain, which for all we know is the most complicated three-pound hunk of matter in the universe – and end with a thoroughly globalized culture and social structure that encompasses all aspects of our species' physical, biological, psychological, social, emotional, cultural, and spiritual lives. We are the most successful species ever to have inhabited the planet; we have colonized every inhabitable piece of dirt; our range extends everywhere; all the earth's resources lay at our command. To record all that has come to be known about human origins, evolution, language, culture, and social structure – everything we know about human emotions, identity, love, religion, family, economics, politics, domination, exploitation, and on through a very long list – would require orders of magnitude more volumes than the mere 26 volumes that comprise the present work.

We have come increasingly to the realization that what is social and human about our species is very intimately connected to our biological, genetic, and evolutionary inheritance. At the same time, the brain specifically and biological evolution more generally "cannot be viewed separately from the material, historical and

social circumstances that produce it" (Berntsen and Baker, 2015). As these authors put it, biology and culture are 'mutually constitutive.' Fifteen years ago, the editors of the first edition remarked on "ferment at the boundaries between the biological and the behavioral and social sciences." And while there are still important controversies, much of the ferment has yielded to cooperation as we are just now beginning to explore this endlessly complex web of interconnectedness between our biological and social selves. It is an easy and nearly inevitable conclusion, thus, that the third edition of the IESBS will contain a great deal more of the work being done at this intersection than 2/e was able to accommodate.

To conclude on a purely personal note, the 5 years I have spent working on this project produced many professional and personal gratifications, none quite so delicious as the certain knowledge that I would learn something new every single day. My work on 2/e exposed me to literature I never knew existed and to aspects of the social and behavioral sciences of which I was at best dimly aware. I can only hope that readers who come to these pages will find them as enriching as I have.

ACKNOWLEDGMENTS

A work of this scale is inevitably a communal enterprise involving many hundreds of editors, authors, reviewers, technical support people, colleagues, professional acquaintances, and friends who have provided input, advice, encouragement, and assistance over the past five years. Any listing is bound to be incomplete, so my apologies in advance to those who expected to be mentioned here but are not. Be assured that the slight is not intentional.

My negotiations with Elsevier about this project began early in 2010. By May of that year, I had committed to the project and have been working on it at varying levels of intensity ever since — often on weekends, during holidays, and whenever else I could snatch a useable chunk of time. So my first acknowledgment must be to my wife Chris for suffering through my five year obsession, always with understanding and affection, usually with good cheer. Chris is probably the only person in the world who is happier than I am that the project is now completed.

I must also acknowledge an enormous intellectual debt to the editors in chief of the first edition of the *International Encyclopedia of the Social and Behavioral Sciences*, Drs Neil Smelser and Paul Baltes (the latter now deceased). Dr Smelser was gracious enough to serve as Chair Emeritus of the project's International Board of Consulting Editors and to put himself at my disposal as, in his words, "a battle-scarred veteran." The basic intellectual structure of this work is adopted more or less wholesale from the Smelser—Baltes edition, with a few exceptions noted earlier in the *Introduction*. Without the original to serve as the starting point and blueprint, it is hard to imagine even embarking on such a task, much less bringing it to completion. Their edition was hailed as "the largest corpus of knowledge about the social and behavioral sciences in existence," which is to say that it formed an *extremely* solid foundation from which to build the work you now hold in your hands.

The first edition was organized into 39 sections overseen by a team of 53 section editors. The structure of the second edition is slightly different. It is divided up into 10 broad 'Areas,' each with an Area Editor overseeing the work of between four and eight Section Editors. In all, the second edition is thus comprised of the 10 Areas subdivided into 53 Sections; the 53 Sections were developed by a team of 76 Section Editors. So whereas Smelser and Baltes had 53 colleagues to help complete the work, I had 84 (two of the Area Editors also edited their own sections). On pages i-v in the front matter to this work one finds an Editorial Board list showing the Area Editors, Section Editors, Sections, names, and affiliations of the entire editorial team — a team whose dedication and effort in behalf of the project has vastly exceeded the rate of pay. A more helpful, productive, or delightful group of scholarly collaborators is difficult to imagine.

What readers see in the listed Editorial Structure of the work is the *final* editorial team as it existed when the work went into production. As would be expected in a project of this duration, there was considerable turnover within the team as the project developed and as death, competing demands, and general indifference all took their toll. I am grateful, nonetheless, to everyone who agreed, at least initially, to participate in the project, whether or not they were able to stay involved to the very end.

Susan Hanson (Geography) and Ulf Hannerz (Anthropology) are owed a special note of thanks because, of the 53 Section Editors involved in the first edition, these are the only two who agreed to reprise their roles in the second. (Both also wisely requested and received coeditors to carry part of the load.) Persuading people to serve who had no real idea what they were getting into was challenge enough, but these two suffered through 1/e and were willing to do it all over again for 2/e. And for that, I am especially grateful.

Many of the editors benefitted from the assistance of colleagues and graduate students at their various institutions. There was no mechanism built into the editorial process to keep systematic track of this

assistance and so the listing below is certain to be incomplete. But I can at least acknowledge those of whom I am aware who contributed time and intellectual energy to the effort: Liam Morton and Andrea Livingstone (Psychiatry); Jennifer O'Connor and Alana Dorris (Applied, Industrial and Organizational Psychology); Jen Hanis-Martin (Sexuality); David Budde, Annette Stimmer, Nikolas Ott, and Franziska Pfeifer (Institutions and Infrastructure of Social and Behavioral Sciences); Matthew LeDuc and Scott Freeman (Contemporary Cultural Concerns); and Simone Dudziak (Public Policy). To those named, my thanks. To those omitted, my apologies.

A special note of thanks to Dr Donald J. Barrett. Don was originally recruited to develop an entirely new section of the second edition on Gay, Lesbian, Bisexual, and Transsexual Studies, completed the section in short order, then e-mailed me to ask if there was anything further he could do to be helpful. Consequently, he took a major hand in developing the section on Biographies and was quite helpful with many other sections too. He appears in the Editorial Structure both as a Section Editor and as a Senior Editorial Associate to acknowledge his yeoman service to the entire enterprise. Also listed as a Senior Editorial Associate is my colleague Dr Amy M. Donley, who has been with the project since the very beginning and who, more than once, was all that stood between me and madness. I am proud to count them both as colleagues, collaborators, and friends.

I am also pleased to acknowledge Don Barrett, Andreas Hess, Harry Whitaker, John Berry, Barbara Miller, Scott Bentley, and Claire Byrne for their incisive and helpful commentary on previous drafts of the Acknowledgments and Editor's Introduction.

The project's International Board of Consulting Editors, chaired by Smelser and Dr Peter Marsden of Harvard University, was formed late in 2011 as a 'sounding board' to be used by the Area and Section Editors in searching for topics and authors and to help push for greater internationalism in our coverage. As it turned out, several members of this Board also stepped up to write entries in their areas of expertise. The composition of this Board and the affiliations of the consulting editors (as they were when the Board was first formed, not necessarily as they are today) are as follows: Neil J. Smelser, *University of California, USA*; Peter V. Marsden, *Harvard University, USA*; Ronald F. Abler, *International Geographical Union, USA*; John Bacon-Shone, *University of Hong Kong, China*; Roberto Briceño-León, *Universidad Central de Venezuela, Venezuela*; Roel Bosker, *Rijksuniversiteit Groningen, The Netherlands*; Michael Burawoy, *University of California, Berkeley, USA*; Nestor T. Castro, *University of the Philippines, Philippines*; Dalton Conley, *New York University, USA*; Freek Cronjé, *North West University, South Africa*; Scott Davies, *McMaster University, Canada*; Abdul Rahman Haji Embong, *Malaysian Social Science Association, Malaysia*; Joan-Maria Esteban, *Barcelona Graduate School of Economics, Spain*; Robert S. Feldman, *University of Massachusetts, USA*; Sari Hanafi, *American University of Beirut, Lebanon*; Gudmund Hernes, *Norwegian Business School, Norway*; Sheila Jasanoff, *Harvard University, USA*; Tim Jensen, *University of Southern Denmark, Denmark*; Colin Jones, *University of London, UK*; Nadezhda Lebedeva, *Higher School of Economics; and National Research University, Russia*; Miklós Lévay, *Eötvös Lorand University, Hungary*; Dinka Marinovic Jerolimov, *Institute for Social Research, Croatia*; Laurie M. Joyner, *Rollins College, USA*; Ferenc Kiefer, *Hungarian Academy of Sciences, Hungary*; Pan Suk Kim, *Yonsei University, South Korea*; Katsuya Kodama, *International Peace Research Association; and Mie University, Japan*; Allan Lavell, *Facultad Latinoamericana de Ciencias Sociales (FLACSO), Costa Rica*; Jake Lynch, *University of Sydney, Australia*; Cecilia Mabragana, *Consejo Nacional de Investigaciones Cientificas y Tecnicas (CONICET), Argentina*; William McBride, *Purdue University, USA*; Ishwar Modi, *University of Rajasthan, India*; Leonardo Morlino, *School of Government, Italy*; Melvin L. Oliver, *University of California, USA*; Angela M. O'Rand, *Duke University, USA*; Kenneth Prewitt, *Columbia University, USA*; Thilo Rehren, *University College London Qatar, Qatar*; Colette Sabatier, *Université Victor Segalen, France*; Philip Schofield, *University College, UK*; Rainer K. Silbereisen, *University of Jena, Germany*; Chamhuri bin Siwar, *National University of Malaysia, Malaysia*; Tom W. Smith, *World Association for Public Opinion Research, USA*; Catalina Smulovitz, *Universidad Torcuato Di Tella Miñones, Argentina*; Philip Spinhoven, *Leiden University, The Netherlands*; Sukhadeo Thorat, *Indian Council of Social Science Research, India*; Nigel Thrift, *University of Warwick, UK*; John R. Townshend, *University of Maryland, USA*; Gisèle Yasmeen, *Social Sciences and Humanities Research Council of Canada, Canada*.

Searching for an editorial team to represent every social science discipline and every region of the globe quickly exposed the deficiencies in my personal network, so I am indebted to a very large number of scholars around the world for calling names of prospects to my attention, allowing me to drop their names in the recruitment effort, or otherwise helping me find people with the expertise and commitment required for the job. In most cases, this is a list of people who were invited onto the editorial team in some capacity,

demurred, but made valuable suggestions about others to contact. In several cases, people are listed because they engaged me in intellectual discussions about the structure, format, and even advisability of this work, or simply replied to a cold-call e-mail in pleasant, kind, helpful, or informative ways. Again ignoring the risk of omission, my sincere personal thanks to those named below for their contributions large and small to the final product:

Doug Anderton, Juri Allik, George Armelagos, Susan Ayers, Amanda Baumle, Janeen Baxter, Jess ben-Habib, Joao Biehl, David Blanchflower, Hans-Peter Blossfeld, Jason Boardman, Dorret Boomsma, Roel Bosker, Henry Brady, Martin Bulmer, Craig Calhoun, Miguel Centeno, William Cockerham, Mark Nathan Cohen, Amelie Constant, Simon Cottle, Connie Citro, Eileen Crimmons, James Curran, Scott Davies, Donatella Della Porta, George Downs, Francis Dodoo, David Dozois, Sonja Drobnick, Jaap Dronkers, John Dryzek, Riley Dunlap, Lauren Edelman, David Elesh, Paula England, Nancy Eisenberg, Geoffrey Evans, Miriam Faust, Robert Feenstra, Marcus Feldman, Stanley Feldman, Ronald Fischer, James Fowler, Jeremy Freese, Angela D. Friederici, Michael Frumpkin, Masahisa Fujita, Nicole M. Gage, Nancy Gallini, Rosemary Gartner, Morton Ann Gernsbacher, Robert Goodin, John Grattan, Lance Gravlee, David Greenberg, Wendy Griswold, Melanie Guldi, Monica Das Gupta, Peter Hatemi, Robert Haveman, Karen Heimer, John Hibbing, Sarah Blaffer Hrdy, Sheila Jasanoff, Kelly Kadera, Cigdem Kagitcibasi, David Kavanaugh, Roger Keil, Byungkook Kim, Rob Kitchin, Jack Knight, Lyle Konigsberg, Candace Kruttschnitt, Helen Ladd, Phillip Lane, Graeme Lang, Janet Lauritsen, Ashley Leeds, Evelyn Lehrer, Richard Lerner, David Lewis, Tim Liao, Tom Linneman, Norman Long, Karen Lyons, Ruth Mace, Gary Marks, Herbert Marsh, Karl-Ulrich Mayer, Lorraine Mazerolle, Rose McDermott, Susan Michie, Harry Minas, Peter Miller, S. Phillip Morgan, Victor Nee, Vin-Kim Nguyen, Paul Nieuwbeerta, Helga Nowotny, Howard Nusbaum, Claus Offe, Thomas Ollendick, Joan Orme, Dennis O'Rourke, Michael Overington, Catherine Panter-Brick, Susan Parnell, Deborah M. Pearsall, Gerard Pfann, Jon Pierre, Mike Ping, Jennifer Platt, Ken Prewitt, Cathy Price, Jill Quadnagno, Charles Ragin, Thilo Rehren, Ben Rosamond, Bo Rothstein, Beth Rubin, Heinrich Sauer, Peer Scheepers, Ralf Schwarzer, Moshe Semyonov, Michael Shanahan, Sara Shostak, Alan Sica, Rainer K. Silbereisen, Beth Simmons, Catalina Smulovitz, Michael Sobel, Diane Stone, Jill Stephenson, Rafe Stolzenberg, Miron Straf, Richard Swedberg, Alan C. Swedlund, Sidney Tarrow, Jacques-Francoise Thisse, Stefan Timmermans, Florencia Torche, Erik Tsang, Judy Treas, Billie Turner, Cees van der Eijk, Paul van Lange, James Vaupel, Karin Wahl-Jorgensen, Mitchell G. Weiss, Neil Whitehead, Pamela Wilcox, Bjorn Wittrock, Cornelia Woll, Gisele Yasmeen, and Barbie Zelizer.

Gratitude is owed as well to the many colleagues at Elsevier who contributed to the production of this volume. My first debt is to Claire Byrne, the project's Content Project Manager and the head of the Major Reference Works (MRW) team that managed the day-to-day *Sturm und Drang* of the project: aggrieved, confused, or delinquent authors, missed deadlines, testy and intransigent editors, and the often-maddening work style of the Editor in Chief. I am sure there were days when Claire wanted to tear her hair out, but to external appearances, she was an island of calm in a sea of turmoil. She was also exceptionally good at her job.

Claire's MRW team comprised Richard Berryman, Will Bowden-Green, Esmond Collins, Mark Harper, Sam Mahfoudh, Mike Nicholls, Gemma Tomalin, Joanne Williams, and Marise Willis. No matter what issue or problem I faced, one of these fine, capable people was always available to step up with a solution, invariably offered in a spirit of cooperation and good cheer. They have been to IESBS 2/e what tech support is to the modern computerized office. Getting this work completed without their help is inconceivable.

Thanks also to the succession of Elsevier's Acquisitions Editors who managed the finances and internal politics of the project: to Scott Bentley, whose gentle suasions pulled me into the project in the beginning; to Karen Maloney and Peter Labella who ran the show in the middle period; and to Lisa Tickner who was in charge at the very end. These are the people on the front line in the endless war between the publisher, who wants things done now and at minimal expense, and the Editor in Chief, who was always asking for more time and more money. The many dozens of amicable compromises necessary to bring the project to completion were all ably negotiated by Scott, Karen, Peter, and Lisa, and for that, I am grateful indeed.

The University of Central Florida and its Department of Sociology have provided a congenial home for the project. My thanks in particular to Dean Michael Johnson; to the current and former chairs of my department, Jana L. Jasinski and Libby Mustaine; to my faculty colleagues Liz Grauerholz, Phillip 'Hutch' Pollock, Bruce Wilson, Melanie Guldi, Stacy Barber, Tosha Dupras, and John Schultz; and to current and former graduate students Thomas Hall, Sara Strickhouser, Betsy Swart, Jordana Navarro, Marie Gualtieri, Shannon Simone, and Shannon Frey.

And most of all, my sincere thanks to the many thousands of authors whose work this is. When comparing the quality of the work contained within these pages to the authors' honoraria, it is obvious that IESBS 2/e is an act of collective charity by our authors to the disciplines they represent. It is my pleasure to thank our authors on behalf of the global social science community.

James D. Wright

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the Encyclopedia is arranged as a series of articles in alphabetical order.

There are four features to help you easily find the topic you are interested in an alphabetical contents list, cross-references to other relevant articles within each article, subject classification index, and a full subject index.

1. Alphabetical Contents List

The alphabetical contents list, which appears at the front of each volume, lists the articles in the order that they appear in that volume of the Encyclopedia. It includes both the volume number and the page number of each article.

2. Cross-references

All of the articles in the Encyclopedia have been cross-referenced. The cross-references, which appear at the end of an article as a See also list, serve three different functions:

a. To draw the reader's attention to related materials in other articles.
b. To indicate material that broadens and extends the scope of the article.
c. To indicate material that covers a topic in more depth.

3. Subject Classification Index

This index appears in Volume 26 and groups articles under subject headings that reflect the broad themes of Social and Behavioral Sciences. This index is useful for making quick connections between articles and locating the relevant article for a topic that is covered in more than one article. Under some section headings, you will find subheadings, if it is appropriate for the articles in a subject area to be grouped into more specific subareas.

4. Contributors

At the start of each volume, there is list of the authors who contributed to that volume.

5. Index

The index appears in Volume 26. The index includes page numbers for quick reference to the information you are looking for. The index articles differentiate between references to whole article, a part of an article, and a table or figure.

Infancy and Childhood: Emotional Development

Ross A Thompson, University of California Davis, Davis, CA, USA

© 2015 Elsevier Ltd. All rights reserved.
This article is a revision of the previous edition article by R.A. Thompson, volume 11, pp. 7382–7387, © 2001, Elsevier Ltd.

Abstract

Emotional development is a uniquely integrative and psychologically constructive feature of psychological growth in infancy and childhood. The role of emotions in behavior and development, and the nature of emotion itself, are discussed in relation to structuralist and functionalist approaches to emotional development. The focus then turns to considering 'what is emotional development the development of?' and the contributions of psychobiological and neurobiological growth, perceptual processes, emotion understanding, the growth of self-awareness and self-understanding, understanding of emotional display rules, and the development of emotion regulation are considered. The article concludes with consideration of the importance of social relationships to early emotional development and future directions for research in this field.

Emotion is a familiar but psychologically complex human experience. Consequently, the growth of emotion integrates diverse developmental processes in infancy and childhood, including psychobiological and neurobiological growth, perceptual processes, emotional and social understanding, self-awareness and self-understanding, and the growth of self-regulation. The study of emotional development has also been stimulated by basic questions concerning the nature of emotion itself and its role in behavior and development. This article explores the issues that have contributed to considerable research interest in emotional growth early in life.

The Nature of Emotional Development

Emotions color the life experience of people of all ages. For infants and children, emotions have especially powerful motivational consequences because emotion understanding is rudimentary, capacities for emotion self-regulation are limited, and the young child's engagement or withdrawal from events is primarily emotional in quality. Emotional development is central to understanding the growth of social competence, intellectual achievement, self-understanding, and the earliest origins of mental health or psychopathology because of the importance of emotion to the organization and regulation of behavior. Emotional development provides a window into the psychological growth of the child as, from infancy to late childhood, emotions become integrated into the broader fabric of behavioral competence, become objects of thought and analysis, can be strategically expressed or concealed in social situations, are shaped by the child's experience of significant relationships, motivate prosocial as well as aggressive tendencies, become part of self-understanding (especially in feelings of pride and shame), and color the individuality of personality.

Emotions and Development

Emotional development was vigorously studied earlier in the twentieth century and has received renewed attention owing to several new theoretical approaches to understanding emotional development. First, emotions are regarded as centrally important to understanding development in infancy and childhood, owing in part to how emotions provide organization and motivation to early developmental achievements. Young children's experience of important social relationships, their emergent understanding of themselves, their motivation to achieve and their responses to success and failure, their understanding of cultural values, and many other central facets of early development are infused with emotion. Second, emotional development offers a uniquely integrative perspective on human development. Understanding emotional growth requires synthesizing biological perspectives on development (including neurobiological growth and neuroendocrine functioning) with social perspectives (including relational and family influences) and the child's developing representations of emotion (including understanding the causes and consequences of emotions, and of cultural norms). Third, emotions are viewed as having constructive as well as disorganizing features. Although emotions are capable of undermining effective functioning (which accounts for current scientific interest in the growth of emotion regulation), developmental researchers also emphasize how emotions motivate and organize young children's understanding of the social world, appraisals of the self, judgments of approved and disapproved conduct, engagement in social conflict resolution, and many other developing skills and capabilities. This is consistent with a new appreciation for the constructive, organizational role of emotions in other areas of psychological study.

Contemporary study of emotional development in infancy and childhood is also motivated by clinical concerns – most notably, a growing realization of the early emergence of emotionally related disorders in young children, including depression, anxiety disorders, and behavioral and conduct problems (Luby, 2006). Thus the study of emotional development is informed by the field of developmental psychopathology and studies of the origins of affective disorders in troubled parent–child relationships, temperamental vulnerability, environmental and genetic risk factors, and individual capacities for emotion self-regulation (e.g., Vasey and Dadds, 2000). This research further underscores the complex, integrative quality of emotional growth and the various risks that can exist for emotional dysfunction, as well as alternative avenues to prevention and remediation.

Developmental research on emotions has required a broad range of methodologies. These include fine-grained analysis of videotaped facial expressions, naturalistic observations of social interaction at home or school, conversations with young children about their comprehension of emotional events, detailed study of the responses of children to emotionally evocative laboratory vignettes, parent-report measures, psychobiological measures of heart rate or cortisol, or brain imaging during emotionally arousing situations. Developmental scientists are increasingly integrating these methodological strategies in broadly based longitudinal research that enables them to study the emergence of emotional capacities over time and in the context of family processes, psychobiological maturation, and other influences.

What Is Emotion?

Contemporary study of emotion in behavior and development is accompanied by debate over the nature of emotion itself (Izard, 2010). Two broad perspectives can be distinguished. The structuralist perspective defines emotion in terms of discrete emotional states, each with unique patterns of subjective feeling, cognitive appraisal, physiological arousal, and facial expression (Izard and Ackerman, 2000). These emotion components are tightly interconnected and are deeply rooted in human evolution because of their relevance to reproductive success (e.g., feelings of anger involve visceral, perceptual, subjective, and expressive components relevant to self-defense). This view is consistent with the everyday tendency to distinguish basic emotions like anger, fear, sadness, and joy as readily dissociable states.

Other theorists advocating functionalist perspectives to emotional development have questioned whether emotional life is so discretely packaged and have offered an alternative view (Saarni et al., 2006). In this perspective, emotion is defined in terms of the quality of the transactions between the person and the environment on matters of significance to the individual. In this regard, what defines an emotion is not a network of internal subjective, physiological, and other components, but rather the constellation of a person's goals, appraisals, action tendencies, and other capacities in relation to environmental inventives, obstacles, and opportunities. As a result, emotional experience is not confined to a predefined set of emotion categories, but can encompass the rich variety of subtly nuanced emotional blends characteristic of everyday experience, as well as the breadth of how emotion is conceptualized in diverse sociocultural groups based on how specific person–environment transactions are conceived.

A functionalist approach is also well suited to developmental analysis. One way that emotions develop, for example, is in how the generalized arousal conditions of early infancy mature into the more specific, organized, and refined emotional states apparent in older children and adults. Young infants do not necessarily experience or express emotions in ways that fit into the discrete emotion categories by which adults conceptualize emotion, but appear instead to experience more diffuse affective systems that become progressively better differentiated as a result of early social experiences and socialization, cognitive growth, and psychobiological maturation. Studying this developmental process requires methodological creativity and breadth, as functionalist theorists suggest. Rather than relying exclusively on facial expressions as primary indicators of underlying subjectivity, for example, developmental researchers increasingly index emotion multimodally, integrating facial, vocal, and other behavioral indicators into an organizational interpretation in relation to the child's interaction with environmental opportunities and challenges. However, the functionalist perspective faces the challenge of a conceptualization of emotion that may be unduly inclusive: it is not entirely clear how emotion differs from other motivated incentives, such as needs and desires. Perhaps for this reason, contemporary emotion researchers have continued to embrace the organized portrayal of emotion coming from structuralist theory, while enlisting the functionalist understanding of these emotions.

What is Emotional Development the Development of?

The primary challenge of developmental analysis is understanding why developmental changes in emotion occur, and how emotional growth is associated with concurrent advances in social, cognitive, linguistic, and physical development. Exploring the various components of emotional development reveals how emotional experience integrates significant aspects of psychological development in infancy and childhood.

Neurobiological and Psychobiological Growth

Emotions are biologically basic features of human functioning. They are predicated on widely distributed and richly interconnected brain structures and hormonal influences that organize the interplay of activation and regulation that constitutes emotional reactions. The young infant's capacity to exhibit distress, fear, surprise, happiness, and rage reflects the early functioning of these biologically deep-rooted neurological and psychobiological systems. Emotional development is based, therefore, on neurophysiological, neuroendocrine, and other biological processes that emerge early and develop over an extended period in childhood (LeDoux, 2000; Panksepp and Biven, 2012). For example, the developing stability of sympathetic and parasympathetic nervous system functioning in infancy helps to account for the growing predictability, manageability, and environmental responsiveness of the infant's emotional responding (Gunnar and Davis, 2003). Later in childhood, as higher brain regions (especially in the prefrontal neocortex) progressively mature and become integrated with early developing regions of the limbic system and other subcortical structures, emotional life becomes increasingly characterized by more acute emotion appraisals, complex emotional blends, and growing capacities for emotion self-regulation. Because an apparently simple emotional reaction is actually a surprisingly complex psychobiological and neurobiological event, developmental changes in multiple brain regions, hormonal functioning, and neurotransmitter regulation are involved in emotional growth (*see* Brain Aging (Normal): Behavioral, Cognitive, and Personality Consequences).

It is important to recognize, however, that lower brain regions (such as the limbic system) governing emotional

activation and higher regions (such as the prefrontal cortex) associated with emotion regulation are typically coactive in any circumstance in which an infant or adult experiences an emotional response. This has two important implications (Thompson, 2011). First, there is never any situation in which emotion is 'unregulated' because regulatory systems are constantly coactive with activation systems. Second, emotional experience arises not only from the 'top-down' regulation of neurobiologically lower activation processes by higher regulatory centers, but also by the 'bottom-up' influence of lower systems on higher cortical systems. The latter can occur, for example, as immediate emotion appraisals arising from limbic structures feedforward to influence the processing of emotional circumstances by cortical systems and their regulatory influence.

Perceiving and Responding to Emotions in Others

Throughout life, emotions are evoked by one's perception of emotion in others. Infants are capable of discerning the emotional meaning in an adult's facial and vocal expressions before the end of the first year, and there is evidence that infants respond resonantly to the sound of another infant's crying even earlier. Moreover, by the end of the first year, infants not only attend to the emotional expressions of adults, but also incorporate the meaning of these expressions into their appraisal of people or circumstances about which the infant is uncertain. This phenomenon is called 'social referencing,' and it is analogous to how people enlist the emotional expressions of others into their assessment of their circumstances (Saarni et al., 2006). In a comparable manner, when a 1-year old encounters an unfamiliar person or object, the sight of a trusted adult's reassuring smile or terrified look (especially if it is accompanied by appropriate vocalizations and other behavior) significantly influences the child's approach or withdrawal tendencies. It appears that the infant 'reads' appropriately the meaning of the adult's emotional expression and its referential relevance to the unfamiliar event.

In the years that follow, advances in emotion understanding significantly expand the young child's capacity to respond appropriately and insightfully to the perception of emotion in others. By the end of the second year, for example, toddlers are more consciously aware of the subjectivity of emotional experience (i.e., another person can feel differently than oneself) and of the causes for others' emotions (Wellman, 2011). This is often manifested when young children are observed comforting a distressed adult or peer, teasing a sibling, during pretend play, or even in humor (Denham, 1998).

In early childhood, moreover, genuinely empathic responses to another's distress can be observed. Initially, young children respond with concerned attention to the sight and sound of another's distress, but empathic responses increase in sophistication and scope in the years following. Early empathy is not reliably accompanied by prosocial initiatives toward the distressed person because empathic arousal is a motivationally complex experience for young children (Zahn-Waxler and Radke-Yarrow, 1990). Young preschoolers have been observed to laugh, tease, become distressed, and even hit a distressed parent, for example, as well as offering comfort. With increasing age and greater understanding of their own efficacy as prosocial agents, empathy becomes somewhat more regularly associated with helping others.

Emotion Understanding

The advances in emotion understanding accompanying conceptual growth enable children to better understand others' emotions, and also their own (Thompson and Lagatutta, 2006). Consistent with growth in their developing 'theory of mind,' for example, 2–3 year olds appreciate how emotion is associated with the satisfaction or frustration of desires (which vary for different people), and 4–5 year olds understand the more complex associations between emotion and thoughts, memories, beliefs, and expectations (Wellman, 2011). These conceptual achievements are important because they contribute to the growing realization that (1) emotions are complexly associated with other mental and motivational states in a person, (2) emotions can sometimes be based on false beliefs or appearances (a peer anticipating a delicious dessert that is actually missing from her lunch bag), and (3) outward emotional appearance does not necessarily reveal underlying emotional reality. People can, in other words, conceal what they are feeling.

In middle childhood, children begin to understand the dynamics of emotional experience, such as how emotional intensity gradually dissipates over time, how particular emotions are related to specific antecedent causes, and how a person's unique background, experiences, and personality can yield unique emotional reactions (Saarni, 1999). By late childhood, children begin to appreciate how multiple emotions can be simultaneously evoked by a single event, such as feeling happy and afraid when performing before a group (Saarni et al., 2006). Despite these conceptual advances, some important features of emotion understanding do not emerge significantly until adolescence, such as an awareness of the psychological causes of emotion in relational experience, the experience of ambivalence or emotional conflict, and a grasp of complex emotional states (e.g., poignancy) (*see* Childhood and Adolescence: Developmental Assets).

Throughout this developmental process, cultural values are integrated into children's emotion understanding and their knowledge of how to interpret, express, and regulate emotional reactions (Cole and Tan, 2007). Because of how emotions are perceived in them and interpreted to young children by parents and others, children from different cultures derive different understandings of the antecedent causes of emotion and the appropriate emotions to experience and express in different social situations. They learn, in a sense, how and what to feel, as well as how and when it is appropriate to express their feelings, and how to understand the feelings of others. In this respect, emotion understanding is part of broader cultural belief systems that children incorporate into their thinking.

Emotion, Self-Awareness, and Self-Understanding

Emotional development is complexly tied to the growth of self-awareness and self-understanding in infancy and childhood. Prior to a dawning awareness of the self as a psychological entity, for example, a young child's emotional repertoire does

not include self-referent emotions such as pride, guilt, shame, and embarrassment. Late in the second and during the third years of life, however, as young preschoolers experience increasing psychological self-awareness (e.g., calling self by name, insisting on 'doing it myself'), these self-referential emotions begin to appear (Lagattuta and Thompson, 2007). As young children begin to see the self as an object of analysis by others, and also by oneself, the simple joy of success becomes pride in achievement, and in response to conspicuous attention, young children increasingly respond with gaze aversion, smiling, and other signs of embarrassment.

Emotional reactions to the self are significantly shaped by the reactions of others to the child. The development of self-referential emotions is advanced not only by growing psychological self-awareness, but also by the young child's increasing understanding of behavioral standards and the ability to apply those standards to an evaluation of personal behavior (Thompson et al., 2006). Guilt derives, for example, from an awareness of how personal behavior has departed from a behavioral standard. Parental reactions are crucial to the young child's dawning awareness and application of these standards of conduct, and indeed the earliest expressions of self-referential emotions commonly occur in contexts where young children can explicitly perceive, or anticipate, parental reactions to their accomplishments or misconduct. With increasing age, children appropriate parental standards that become the child's own internalized expectations for conduct. Thus the manner in which parents convey, reinforce, and attach emotional and relational significance to a young child's achievements or misbehavior is an important influence on the child's emotional life, and developing self-esteem and self-concept.

This underscores the complexity of the association between self-understanding and the growth of self-referential emotions. A dawning psychological self-awareness is necessary, in other words, before self-referential emotions become part of a young child's emotional repertoire. Once these emotions have developed, however, the circumstances in which they are elicited and their relational consequences are significant influences on further growth in self-concept and self-understanding.

Emotion and Emotional Displays

One consequence of young children's developing understanding of the difference between belief and reality is the growing realization that emotional expressions may not accurately reveal underlying emotional reality. This awareness emerges at the same time that children discover the social expectations governing emotional expressions. A person is supposed to show delight when opening a gift in the presence of the gift giver, for example, even if the gift is undesirable. This and other emotional 'display rules' governing the expression of emotions in social situations prescribe how emotions are used to avoid hurting others' feelings, protect self-esteem, and preserve relationships.

Young children do not understand display rules, but they can be observed using them as young as age four. Not until middle childhood do children grasp the nature and purposes of emotional display rules, but once they do so they can enlist them in their interactions with family members, peers, and others (Saarni, 1999). As they do so, children also begin to appreciate the privacy of emotional experience: emotions need not necessarily be conveyed to others if one can manage emotional experience and its expression.

The Development of Emotion Regulation

One of the important differences between infants and adolescents is in their capacities for emotion regulation. Emotion regulation is distinct from emotional display rules because although the latter regulate the *expression* of emotion, the former manages emotional *experience*. People have many reasons for managing their emotions: to feel better under stress, elicit support from others, act courageously, resist bullying, enhance motivation, think better, and for many other reasons. Although the goals underlying emotion regulatory efforts are easily understood in very young children, these goals become increasingly complex and nuanced in the more complex social situations of older children. Competent emotion regulation may be observed, for example, when a child loudly protests a peer's provocations when adults are nearby, but quietly tolerates the bully when adults are absent. However, in conditions of risk for developmental psychopathology, such as family violence or child abuse, the goals underlying a child's emotion regulatory efforts may be complex, mutually inconsistent, and thus, in some senses, self-defeating (Thompson and Goodman, 2010).

In infancy, emotions are primarily regulated by others, especially parents. Parents manage a baby's emotions by directly intervening to soothe the child, and also by regulating the emotional demands of familiar settings like home or child care (often in accord with their perceptions of the child's temperament), altering how the child construes an emotional arousing situation (such as by smiling reassuringly when a friendly, but unfamiliar, adult approaches the child), and later by actively coaching young children on expectations or strategies of emotion management. More broadly, the security that young children derive from their emotional attachments to caregivers is an important resource for emotion regulation because of the confidence it inspires that events will not be uncontrollable and that the adult will intervene helpfully when necessary (Thompson, 2011). Emotion regulation is fostered by others, in other words, not only by their immediate interventions, but also by the reassurance provided by the child's relationship with a caring adult.

From an early age, however, young children are also developing rudimentary skills for managing their own emotional experience (Thompson and Goodman, 2010). This can be observed initially in the comfort-seeking of a distressed infant or toddler, and skills of emotion self-regulation expand considerably in early childhood. Young children can be observed making active efforts to avoid or ignore emotionally arousing events, changing or substituting goals that have been frustrated, redirecting activity or attention, using distraction, engaging in encouraging or reassuring self-talk, obtaining further information about the situation, or enlisting other simple behavioral strategies. In the years that follow, moreover, older children become increasingly proficient at enlisting psychologically more sophisticated strategies of emotion

regulation, such as using emotion-blunting ideation, redefining the situation (or attributions for behavior), or acting in a manner inconsistent with felt emotion. The growth of strategies for emotion self-regulation occurs in concert with the development of emotion understanding and children's increasing psychological self-awareness, and contributes to developing social competence with peers and adults.

Relational Influences on Emotional Development

Emotions are not just the outward expression of an internal experience, but are deeply influenced by the social contexts in which they occur. Emotional development illustrates how early in life, intrinsically human and biologically fundamental response processes take shape in a social context.

Social influences on emotional development are especially apparent in children's close relationships with caregivers and other adults. Many things happen in their relationships with adults that guide the course of children's emotional growth (Dunn, 2003). Early in life, the responsiveness of caregivers to a baby's emotions influences the frequency, persistence, and intensity of the infant's emotional signaling, as well as the baby's developing confidence in the adult's helpful assistance. The adult's emotional expressions influence the child's emotional and behavioral responses to events, in a phenomenon earlier described as social referencing. Parental behavior is often also a catalyst for empathic responding, especially when parents fix the attention of offspring on another's distress and carefully explain the causes of that person's feelings. As earlier noted, the behavioral standards that parents convey in their responses to good behavior and misbehavior shape the earliest experiences of pride, guilt, shame, and embarrassment, as well as developing self-concept and self-esteem. More broadly, the simple conversations shared by parents and their young offspring about the day's events help to color and socialize emotion understanding by how the parent describes and explains emotional experiences, attributes motives and emotions to people, and interprets the emotional experiences they have shared (Thompson et al., 2003). Among the many things children learn from these conversations are the sociocultural rules governing emotional expressions in social situations. Finally, adults in close relationships are influential as they directly manage the emotional arousal of young children, and as they coach (and model) the child's use of personal strategies for emotion self-regulation.

Beyond these specific influences, the broader quality of the parent–child relationship provides a context of security and confidence, or of insecurity and uncertainty, that colors emotional growth and the development of emotion self-regulation (Sroufe et al., 2005). In the security or insecurity of the parent–child attachment relationship that begins in infancy and continues throughout childhood, young children experience reassurance that emotions are constructive, enlivening, and manageable facets of life experience through the support of others, or instead learn that emotions are potentially overwhelming and undermining experiences that are faced alone.

Because of the importance of these relational influences, the 'emotional climate' of the home is a significant influence on early emotional development (Gottman et al., 1997). The emotional climate is significantly shaped by sociocultural values, for example, that guide how emotions are socialized and how children learn to interpret their emotional experiences (*see* Socialization in Infancy and Childhood). In more extreme conditions, unfortunately, the home climate is characterized by the emotional turmoil created by marital dysfunction, coercive or abusive parental conduct, or the adult's affective or substance abuse problems. In these circumstances, caregivers not only fail to be sources of emotional support for the child, but they also contribute to emotional demands that most young children find difficult to manage and which are, for many, potentially overwhelming (Thompson and Goodman, 2010). As a consequence, children are themselves at risk for emotional disturbance resulting from their inability to cope with the emotional demands they face, together with their enmeshment in the emotional turmoil of their caregivers, their heightened sensitivity to cues of emotional arousal around them, and their exposure to a compelling model of emotional dysfunction in the adults they live with. Sadly, studies of such children illustrate further the importance of close relationships to healthy emotional growth.

In more constructive family environments, by contrast, parents contribute to the child's growing ability to understand and enlist emotions constructively in social relationships, and enjoy emotional experience personally. In other words, they contribute to the growth of emotional competence (Saarni, 1999).

Future Directions

This aricle reflects two themes that will guide future research on emotional development. The first concerns children's developing representations of emotional experience, especially as they predict children's responses to emotionally arousing events. How do children understand emotion and its influence upon them, and how does this affect their efforts to manage emotion and respond adaptively to situations that evoke emotion? How do these representations change with age and in concert with changes in other representational abilities? The second theme concerns the developing neurobiological foundations of emotion and emotion regulation in children. In what ways are developing neurological, neurohormonal, and psychobiological processes relevant to the child's evolving capacities related to emotional experience, emotional responding, and the management of emotional arousal. Future research on both questions will advance understanding of emotional development and its applications to clinical and other practical issues.

Infancy and Human Development

Abstract

Infancy, which encompasses only a small fraction of the average person's expected life span, is a period characterized by astonishing biological, psychological, and social changes. This article first briefly overviews the history of theory and research in infancy and then discusses whether infancy is a 'stage' of life. Challenges infants pose to their study are next reviewed. Although infants pose special challenges to research, human infancy has been studied as a platform for hypothesis and theory testing; as a major period of physiological and psychological adjustment; as a time of socialization; for infants' effects on adults; as a basis of phylogenetic and ontogenetic comparison; and as a setting point for the balance of the life course. This article presents a catalog of multiple types of infancy studies and concludes with a consideration of the general significance of human infancy.

Introduction

The period in the life cycle called *infancy* has been variously defined by educators, lawyers, and social and behavioral scientists. However, the Latinate root of infant, *in + fans*, ties the definition to a psychosocial status, viz the absence language, rather than to educational requirements or vagaries of legal opinion. Infancy roughly brackets the first 12–18 months of postnatal life. Several poignant and telling observations have been made about this period: All of us have been infants, yet mysteriously the mental, emotional, and social life of our infancy is completely lost to us. Infants are irresistible to our senses (*Who is not enchanted by the smell of a baby's head?*), engaging of our intellect (*What are you thinking little one?*), and moving to our emotions (*Who can resist responding to a baby's cry?*). Infants are completely dependent and under our care, and the results of our actions toward them become embodied in them. Infancy represents a deeply resonant beginning in which much is invested theoretically, psychologically, and personally.

Infancy encompasses only a small fraction of the average person's expected life span, but this period is characterized by astonishing biological, psychological, and social changes, many of which are evident even on casual observation. Within this brief phase, infants' length and weight multiply and they move from feeding dependence to being weaned; infants change from immature beings unable to move limbs in a coordinated manner to toddlers who can purposefully control complicated sequences of muscle contractions and flexions necessary to grasp and walk; the infant matures from unintelligible babbler to sentient being who can make needs and wishes abundantly clear verbally. Explaining these many transformations from infancy to maturity constitutes one of the challenging tasks confronting philosophy, biology, and psychology.

A major impetus to the formal and scientific study of infancy came from Charles Darwin who published in *Mind* "A Biographical Sketch of an Infant," an account of the infancy of his firstborn son William Erasmus (Doddy). Darwin's foremost roles in the origins and descent of infancy studies, developmental research, and comparative science sparked continuing interest. In the years following Darwin's (1877) publication, a plethora of baby biographies appeared, and the study of infancy came into its own (Bornstein et al., 2014).

Baby biographies that followed on Darwin's heels in the late nineteenth and early twentieth centuries provided a wealth of ideas about infants, and the evidence developed from them had two important implications. First, baby biographies recorded that infants of different ages were competent at different tasks, and, second, baby biographies revealed the existence of considerable individual variation among infants of the same age. On these observations, scientists eventually developed standardized assessments for infants, and their sequences, scales, and schedules helped further define normal early human development. A landmark example was Nancy Bayley, who in the 1920s began to measure mental and motor growth in infancy systematically. Bayley developed the *California First Year Mental Scale*, now the widely used *Bayley Scales of Infant Development*. Around the middle of the twentieth century, mothers also began to bring their infants to university and governmental laboratories for study. Among the notable progenitors of scientific infancy studies was Robert Fantz, who instigated two techniques – habituation and novelty preference – which essentially broke the communication barrier that separates infants from the rest of us and ignited a revolution in understanding infancy.

Our ever-burgeoning knowledge about infancy since has been compiled periodically, and over the last half-century articles, essays, chapters, monographs, and books on infancy have appeared at a quickening pace. Milestones in the literature on infancy include Kessen et al.'s (1970) *Infancy: A Bibliography and Guide*, a survey that appended more than 2000 references to works on infants appearing at that time. Stone et al.'s (1973) *The Competent Infant* excerpted eclectic important works to that date. Among the notable contemporary treatments focused on academic (not trade) approaches to infancy are Fogel's (2010) *Infant Development*, Bremner and Wachs's (2010) *Handbook of Infant Development*, and Bornstein et al.'s (2014) *Development in Infancy: A Contemporary Introduction*. Several scientific journals, *Infancy*, *Infant Mental Health Journal*, and *Infant Behavior*

and Development, are now devoted exclusively to reports about infancy.

Is Infancy a Stage of Life?

Theory in the biological and social sciences is undecided about whether human development over the life course is gradual and continuous or saltatory and best described by discontinuous stages. Do human beings develop in the way an acorn becomes an oak or as a caterpillar becomes a butterfly? For most developmentalists, the answer to this question turns on predilection and emphasis. In Medieval times, infants were conceived of as miniaturized adults, and the American philosopher psychologist William James (1890: p. 237) opined that human development is continuous, "without break, crack, or division." In development it seems often to be the case that the new absorbs and builds on the old, and so ontogeny seems more like a scale.

At the same time, some constructs, structures, functions, and processes in infants appear to undergo discrete changes. A stage is thought to represent a unique pattern of interrelated features and to differ qualitatively from other patterns that identify other stages. Stages constitute a kind of organizing principle and are used conventionally to compare and contrast assorted aspects of development at one period or between periods. Dividing the life cycle into stages (variously called ages, phases, and periods) is challenging and subtle, and both theoretical and historical currents shape professional and popular opinion on the topic. Stages help make sense of life; they indicate that there are developments and experiences that merit attention in their own right and in terms of their contributions to subsequent development. Many outstanding developmental theorists – Freud, Piaget, Erikson, and Werner – have championed stage theories of development, and all identified infancy as one. Thus, in the minds of many, human infancy possesses an independent status and quality, even if its starting and end points are a bit uncertain. For them, the core of infancy defines a life stage based on biological, cognitive, and social data. Infants do not speak, children do; infants are fed, children are weaned; infants creep and crawl, children walk and run. Social convention also has had important things to say about the distinctiveness of infancy. "… a primary function of culture in shaping human experience is the division of the continuum of human development into meaningful segments, or 'stages.' … All cultures, so far as we know, recognize *infancy* as a stage of human development" (Harkness and Super 1983: p. 223). Indeed, infancy itself has been subdivided into stages. Perhaps, the best known are the six stages described by Piaget, but many developmental scientists since have hypothesized that 'biobehavioral shifts,' 'psychic organizations,' 'developmental crises,' and the like take place during infancy.

All that said, some theorists question the utility of the stage concept, noting that stage theories are descriptive rather than explanatory; stages downplay individual differences and may not contribute to understanding individual development; and stages are often general and idealistic, whereas life is replete with variation and inconsistency. As stated, idiosyncratic prediction and emphasis prevail in this domain.

Challenges to Studying Infants

How much we have learned about infants' behavior and development since Darwin is testimony largely to the creativity, patience, and persistence of researchers in meeting and overcoming the many formidable challenges posed by infants. First and foremost, infants are (by definition) nonverbal (but not, of course, noncommunicative), and they are also, especially in the early months of life, subject to rapid fluctuations in behavioral state, motorically incompetent, and emotionally labile. Unlike adults, infants are not motivated to perform for researchers. Infants' short attention spans, limited response repertoires, and inherent variability are just a few of the other problems that vex investigators.

Yet, infants are also important and attractive to study, for a host of reasons. The impediments infants present have stimulated researchers to develop strategies geared to overcome the communication barrier (as well as other challenges) that naturally and infelicitously separates infants from the rest of us. Through decades of intensive investigation, infants have slowly divulged many of their secrets. In the view of some, this glimpse into the heretofore private world of infancy, and what it portends for the future, represents one of the impressive achievements of modern behavioral and social science.

Domains of Infancy Studies

Infants contribute to biological, psychological, and social knowledge in several major ways.

A Platform for Theory Testing

Because infancy is a period of life that precedes the onset and influence of (much) experience, traditional 'nature–nurture' debates about mental and moral development have persistently turned to infancy for thought experiments and field studies, and different grand theories made specific (and sometimes) testable predictions about infants. What do we know before we have any experience in the world? What kinds of knowledge require what kinds of experience? Infancy has long been a platform for theorizing and hypothesizing.

Philosophers from Plato to Jean-Jacques Rousseau and W.V. Quine directly appealed to infancy for answers to questions that seek the origins and nature of human knowledge. Extreme views on epistemology were proposed by empiricists, who asserted that all knowledge derives from the senses and grows by way of experience; and by nativists, who reasoned that some kinds of knowledge cannot possibly rely on experience and thus human beings must enter the world with a mental apparatus equipped (at the very least) to order and organize their percepts and cognitions.

Empiricists contend that there is no endowed knowledge at birth, that knowledge is learned, and that development proceeds through experience and association. The empiricist's view of the nature of the mind early in life can be characterized by two separate, though conceptually related, schools of thought. One derived from John Locke (1632–1704), who in *An Essay Concerning Human Understanding* (Book II, Chapter 1.2) described the mind at birth as a 'white paper': Mental life

begins 'without any ideas,' and understanding the world depends wholly on the accumulation of experiences. A slightly different empiricist view can be attributed to William James (1842–1910), who in *Some Problems of Philosophy* (1924: p. 50) described sensible life as a big 'blooming buzzing confusion' out of which experience organizes and creates knowledge and order. According to empiricist beliefs, the naive infant does not share the same world of the experienced adult. Empiricism is inherently developmental because, by whatever mechanism postulated, human beings grow from immature to mature.

By contrast, extreme nativists postulated that human beings are not 'created' mindless and that the knowledge that humans possess cannot be achieved by learning alone in so short a span of time as infancy or even childhood. As a consequence, philosophers like René Descartes (1596–1650) and Immanuel Kant (1724–1804) conceived of humans as endowed from birth with 'ideas' or 'categories' of knowledge. The nativist program holds that the human mind naturally and from the beginning of life imposes order on experience, and infant and adult share many capacities. For those abilities that are congenital, nativism is not a developmental view; for those abilities that mature, however, nativism is developmental in outlook.

When psychology turned from nineteenth-century philosophical speculation to twentieth-century empirical investigation, Myrtle McGraw's studies of Johnny and Jimmy; Arnold Gesell's *Atlas* and *Embryology of Behavior*; Jean Piaget's attentiveness to his own three infants: Jacqueline, Lucienne, and Laurent; John Watson's immortal pronouncements on the determinism of association; B.F. Skinner's demonstrations of his daughter in a box; and John Bowlby and Mary Ainsworth's identification of pervasive and enduring effects of attachment drew serial notice to infants as proofs for one or another theory. This tradition continues in comparisons of monozygotes and dizygotes reared apart or treated differently from infancy, in tracing the long-term consequences for children removed from the dire straits of orphanages before or after the end of infancy, and so forth. Infancy continues to provoke enduring philosophical, biological, social, and juridical debate and question. When is the developing fetus a child? When do legal rights of an individual begin?

A Period of Multiple Adjustments

A principal task of infancy is radical physiological and psychological adjustment from the close comfort and complete fulfillment of the intrauterine environment to the deprived, kaleidoscopic extrauterine universe. Save death, the transition from fetus to infant is one of the most abrupt and thoroughgoing adaptations in the life cycle, invoking changes in a constellation of pulmonary, thermoregulatory, and vegetative capacities – not to mention the need to cope with and make sense of the torrent of new sights, sounds, and smells. In many ways, infants are well prepared for this transition to new people and things and for their novel requirements; in a host of other ways, babies are surprisingly ill-prepared. On the one hand, just the way infants look, not to mention their spontaneous and reflexive cries and smiles, draw caregivers near and adaptively maintain caregiver proximity, and infants are notoriously quick learners. Most infants are competent – the transition has been completed successfully by every reader of this sentence. On the other hand, human infants are altricial, and not precocial, animals. As the analyst D.W. Winnicott (1965: p. 39) wrote, "There is no such as an infant." Infants do not and cannot exist outside the infant–caregiver symbiotic system. Of course, infancy is still only a single step on the lifelong path of continuing adjustments.

One concern of infancy study is therefore delineating the status of different characteristics (constructs, structures, functions, and processes) at the beginning of extrauterine life. Focusing on characteristics so close to the beginning of life, investigators of infancy are also naturally interested in how biological and experiential forces fuse to shape our origins as well as inflect the course of our future development. For example, the sensory systems are brain matter, and they do not lie dormant until suddenly 'switched on' at birth; rather, they begin to function before birth. Determining how and approximately when the senses begin to function is important for several reasons. One is that knowing about development of the sensory systems enlarges our understanding of the general relation between structure and function. A second reason is that it is practically (as well as theoretically) important to learn whether and how early brain development is influenced by experience. Preterm babies, born before their expected due date, are exposed to environmental stimulation from which they would normally be protected. If the sensory systems are not functional prenatally, preterms would be protected; if the sensory systems function, however, then preterm babies might be adversely affected by the hyperstimulating environment of the Neonatal Intensive Care Unit.

A Time of Socialization

Adults wield extraordinary and nearly limitless control over infants in part because infants are helpless and in part because infants are plastic to experience. Aside from their genetic bequest, biological parents (just as do social parents) exercise continuing and powerful sway over infants in their roles as ministrators, socializers, and educators. Adults in the infant's immediate environment govern the child's early biological, perceptual, cognitive, and social development by organizing the child's environment, by stimulating, educating, and commanding contingencies. Proximally, many parental decisions of everyday life, from breastfeeding to bowel training, are wholly out of the baby's control but are likely determinative of infant (and possibly future) life nonetheless. Distally, parental sociodemographic characteristics, such as their educational accomplishment, social class, ethnicity, culture, and nationality, determine the lifelong possibilities and prospects for infants, not to mention a child's very chances of surviving infancy. It has been observed that the most significant thing a parent does for an infant is to determine where the child is born (Weisner, 2002). These considerations all betray a perspective of infants as lacking agency, and infants do, but only in proactive degree.

An Exhibition of Agency

Human infants are actually powerful stimuli to adults. Breaking out of a narrow diode top–down view of socialization

focused singularly on adult effects on infants, Richard Bell (1968) inevitably identified many reciprocal 'offspring effects' on parents. Infants feature prominently in this revisionist view. Alone and as a species, infants exert primary direct effects and exhibit secondary indirect effects. The baby's very stature and physiognomy (as mentioned) are compelling. The ethologist Konrad Lorenz (1943) observed that *Kindchenschema* ('babyishness'), the infant's exaggerated head in proportion to the remainder of a short body, bulbous forehead, large eyes, and rounded cheeks, constitute sign stimuli that automatically elicit solicitude in adults. Experimental studies in neuroscience and behavior since support this assertion: The brains of adults (even nonparents who are strangers to the infants depicted) respond quickly and unconsciously to pictures of human infants as opposed to human adults and infant and adult nonhumans as positive and special (Caria et al., 2012; Esposito et al., 2014; Senese et al., 2013). Equally potent and direct are infants' smiles and cries, the one promotes proximity and triggers positive emotions, and the quality, tone, and resonance of the other brooks no excuse or delay in responsiveness. Infant cry has specific and direct effects on adult nervous systems causing blood pressure and skin conductance changes (LaGasse et al., 2005), and eliciting their own unique responses deep within the adult brain (Ranote et al., 2004; De Pisapia et al., 2013; Seifritz et al., 2003). On these bases, infants are unabashedly pressed into service around the world to elicit sympathy, as dependable aids to begging, for example. When Lewis and Clark undertook their renowned nineteenth-century 'Corps of Discovery' of the American west, they included Sacajawea – a Shoshone teenager with a 2-month-old baby strapped on her back. Why? William Clark recorded in his journal that native tribes they met along the way would be inclined to believe that their party was friendly when they saw Sacajawea because a war party would never travel with a woman with a baby (Ambrose, 1997). On a grander scales, almost no society (unless under extreme economic duress) fails to provide infants with the care and attention requisite to their survival. Not infrequently, infants have prodded historical or sociopolitical events; the birth of a child ensures "the line" (Bauer, 2010). Infants likewise powerfully affect women and men in their artistic and scientific work: Infants stimulate song, poetry, literature, humor, art as well as laboratory work. On an individual scale, a newborn constitutes evidence of womanhood and manhood, rousing pride and psychological security. Babies also reorganize the family, provoking mutual commitment and radically altering family economy.

Finally, infants affect their own development. Insofar as people are agents in their own lives (Elder et al., 2015), individual differences in intellect and temperament among infants change those who interact with them.

For purely heuristic purposes, this article separates the otherwise inextricable mutuality between infants and adults into putative 'effects on' and 'effects of.' However, transactions rule life. Modern constructivist theories posit the intricate and permanent interplay of action and experience in the world. How much the infant suckles influences a mother's lactation as much as her lactation influences how much the infant suckles; the level at which parents pitch the complexity of their speech to infants depends on the infant's display of understanding, and infants' understanding depends on the complexity of speech addressed to them.

A Basis of Comparison

Infancy is a natural basis of comparison, and comparisons of many kinds have occupied the attention and interests of infancy investigators. Phylogenetic comparisons contrast different species, and two kinds of infant phylogenetic comparisons are common. One straightforward ethological motive compares human infant abilities, behaviors, and development to those of infants of other species. For example, the rate of brain development in monkey infants outstrips that of human infants. Monkey infants develop faster than human infants, in about a 4:1 ratio (monkeys do in 1 month what a human does in 4 months; Gunderson et al., 1993).

Because many sorts of experimentation with human infants fall outside of ethical bounds, the other phylogenetic comparison uses infant animal models to manipulate contingencies on development, as for example to explore the roles of different kinds of experience in development. Harlow's (1958) renowned studies with infant monkeys illustrate this application. Harlow raised infant monkeys in isolation with one of two mother 'surrogates': One of these 'mothers' was made from wire mesh and had an attached milk bottle from which the monkey could nurse, and the other 'mother' had a soft toweling surface but did not deliver any food. When they were frightened, infant monkeys preferred the cloth mother and held it tightly – in spite of the fact that the wire mother was their only source of nourishment. When these infant monkeys were later put into an unfamiliar environment, they would use the cloth mother as a 'base for operations.' Likewise, experiments based on other sorts of deprivation and cross-fostering can be undertaken with infant monkeys, but not humans.

Other types of comparisons focus on human infants per se and include babies born with or into different circumstances (preterm vs term, adopted vs nonadopted, breastfed vs formula fed). Finally, direct infant–adult ontogenetic comparisons are common (Bornstein et al., 2011); ontogenetic comparisons contrast different stages of life. These include developmental comparisons of mature versus immature status or function. Studies of infancy also provide baseline data against which the normal course of maturation as well as effects of experience into adulthood can be assessed. The human infant is recognized today as 'perceptually competent'; determining just how perception functions in infancy helps to specify the effective perceptual world of babies. If a substance tastes sweet to adults, we may readily suppose that it tastes that way to infants, and even that infants will like it; in fact, however, taste receptors for sweetness may not even be present in infants or, if present, may not function or signal the same perception or quality to infants as to adults.

A Setting Point for the Life Course

Last, infancy has been studied as a basis of stability and change of future development. Development is most readily associated with change and growth (Wohlwill, 1973). As the child rapidly emerges out of the infant, growth and change in many

developmental characteristics are prominent and observable. The complements to growth and change in development are stability and continuity (Bornstein and Bornstein, 2008). Somewhat paradoxically, consistency is more parsimonious and orderly than is transformation. Many features of human development remain (more or less) consistent over time. Biological forces generally tend to reinforce homeostasis in the individual, and the consistent social network in which infant development normally transpires also contributes to stability. Thus, individual–environmental relational processes tilt to promote stability.

Transformation and constancy across time occur at both group and individual levels (Hartmann et al., 2011), and group mean-level consistency or inconsistency (continuity/discontinuity) are complemented by individual-order consistency or inconsistency (stability/instability). The measured mean value of a given characteristic plotted across age defines the developmental function of that characteristic. It may change or remain the same. By contrast, stability describes consistency in the relative ranks of individuals in a group with respect to the expression of some characteristic over time (Bornstein and Bornstein, 2008). For example, a stable characteristic would be one that some infants demonstrate at a relatively high level at time 1 and again at time 2. There are different types of stability. Homotypic stability describes maintenance of rank-order status on an identical characteristic from time 1 to time 2 (e.g., vocabulary size at 12 months and at 4 years). Heterotypic stability describes maintenance of rank-order status between two related, but not identical, characteristics, often related because they presumably share the same underlying process (e.g., vocabulary at 12 months and storytelling at 4 years).

Stability and change tell us about the nature and overall developmental course of a characteristic. Whether individuals maintain their order on some characteristic through time informs not only about individual variation, but contributes to a deeper understanding of the origins, nature, and future of the characteristic as well. Insofar as a characteristic is ontogenetically stable, we know that infants who do well or poorly in that characteristic at one time are likely to do well and poorly again later. Moreover, stable early characteristics can be expected to shape later emerging ones. Infants who know more words at 1 year tend to know more words at 2 years, and 2-year-olds who know more words may be at a long-term advantage because knowing more words speeds learning to read, improves verbal comprehension, and eventuates in better oral language skills (Marchman and Fernald, 2008).

Thus, stability and change have meaning for the more general significance of infancy. The life span perspective in developmental science specifies that human beings are open systems, and the plastic nature of psychological functioning ensures both stability and change across the life course. Significantly, immaturity after birth is marked in humans, and the elongation of infancy permits ample time to develop skills and sample experiences from the environment. In turn, both promote greater behavioral flexibility and adaptive function. Many developmental processes are therefore Janus-like with stable and unstable, continuous and discontinuous aspects. Both stability and change confer advantage. Consider how life might best engineer a human infant. Certainly, we would not want to see the infant's intelligence, personality, what have you fixed in advance of any actual experience. It would be shortsighted and counterproductive to rule out possible effects of experience because adequate development mandates the ability to adapt successfully to the effective surrounding environment. By the other side of the same token, however, we would not want to leave development wholly to the whims of experience because individual experiences can vary so much. A fundamental conceptual issue that has framed debates in theory and research across the history of developmental science has concerned questions of stability and change. In fact, both of these design criteria appear to be met in the evolution of development from human infancy.

The Significance of Infancy

Whether infancy is 'significant' has engendered intense debate between two polar points of view. Some contend that infancy is not particularly important because the status of the infant or experiences in infancy have little (if any) long-term predictive meaning. That is, infant characteristics and experiences are supplanted later in development. This position emphasizes discontinuities and instabilities between infancy and maturity. In this view, infancy is disconnected from the balance of the life course, and infant characteristics and experiences are peripheral or ephemeral, in the sense that they exert little or no enduring effect on later development (Clarke and Clarke, 2000; Kagan, 1998; Lewis, 1997). Empirical support for models that invest more in contemporary status and experience typically consists of failures of early experiences and interventions to show sustained effects as well as demonstrations of the recovery of function from early enrichment or deprivation.

However, other theories contend that infancy is part of a seamless or continuous lifeline and that characteristics and experiences in infancy are important in themselves and are also crucial to later development. Since the time of Plato (*c*.350 BC), philosophers and scientists alike have considered infancy to be uniquely important, and folk wisdom (*As the twig is bent, so grows the tree*) and poetry (*The Child is Father to the Man*) alike express the conviction that early life experiences shape later development. Arguments for the specialness of infancy in this way derive from a diverse and impressive array of theoretical starting points, including psychoanalysis, behaviorism, constructivism, ethology, neuropsychology, attachment, and systems theory. For these theorists, social orientations, intrapersonal proclivities, and intellectual predilections established in infancy set influential, if not enduring, patterns (Bornstein, 2014). For example, Sigmund Freud (1949) focused attention on infancy, suggesting that the ways people are treated in infancy establish lifelong personality traits, and Erik Erikson (1963) also contended that experiences in infancy have implications for the way a person negotiates successive stages of development. For learning theorists like John Watson, B.F. Skinner, and John Dollard and Neal Miller, experiences in infancy are important because they occur first, have no competing propensities to replace, and thus promote

easy and rapid learning. Moreover, they asserted that early and simpler behavior patterns laid down in infancy underlie later and more complex behavior patterns acquired in maturity. What is experienced or learned first often has lasting influences, and infants seem to command an extraordinary facility for learning. Jean Piaget opined that more advanced developmental capacities build on more elementary ones constructed in very early life. Likewise, ethologists and embryologists from Konrad Lorenz and Niko Tinbergen to Stephen J. Gould and Gilbert Gottlieb emphasized the lifelong reverberations of early experiences (as in sensitive periods; Bornstein, 1989) that tend to occur in infancy. The immature nervous system appears to be especially plastic; it can be shaped by experience and its infant character affects the subsequent trajectory of development. Neoteny (the prolongation of infancy, especially in human beings) may have important adaptive significance. John Bowlby, Mary Salter Ainsworth, and their successors (Sroufe et al., 2005) hypothesized that attachment experiences in infancy augur future personality, social, and cognitive development. Even modern systems theorists contend that development consists of hierarchically organized characteristics that incorporate earlier emerging ones that increasingly differentiate over time (Lewontin, 2005). All of these perspectives imply that infant state and experience may disproportionately affect the course of subsequent development.

The development that takes place during the short 635 days after conception – roughly, the prenatal period and the first year – is as or more dramatic than any others in the human life span. The most remarkable developments involve the changing shape and capacity of the body; the complexification of the nervous system; the dawning of sensory and perceptual capacities; the increasing abilities to make sense of, understand, and master things in the world; the achievement of communication; the emergence of characteristic personal and social styles; and the formation of specific social bonds. At no other time is development so fast paced or thoroughgoing in so many different spheres of life. Yet, like Theseus's ship, at the core of the infant and later the toddler, child, adolescent, and adult, is the same individual, and some stability from infancy is expectable.

Summary

On first observation, newborns and infants appear to be erratic and disorganized. At every moment, babies seem to be constantly moving all body parts without apparent purpose; and observed over longer periods, they seem to move unpredictably between sleep and alertness. However, infants are not quite so random. Close and consistent inspection shows that infant activity is actually organized and rhythmical. Some infant actions regularly cycle at high frequencies, perhaps once or more every second. Heartbeats, breathing, and sucking illustrate fast biological rhythms that maintain life, and kicking and rocking exemplify other fast-cycling behaviors. General movements of the body cycle at intermediate rates, once every minute or so. States of waking, quiet sleep, and active sleep cycle at low frequencies, in periods of up to 24 h. By observing over extended times and carefully decomposing infant activity states, it is possible to detect regularity underlying infants' seeming randomness. What we see in the infant at any one time is only apparent irregularity; much of infant behavior is characterized better as underlying regularity, the simultaneous and independent cycling of many complex rhythms.

Understanding infancy better has several implications. First, it has meaning for developmental science in terms of more fully describing the growth of individuals. Second, it is important for more completely understanding the nature and structure of biological and psychological characteristics. Infant development is governed by genetic and biological factors in combination with experiences and environmental influences. Thus, the status and development of any characteristic are attributable to factors in the individual that transact with factors in the environment. Third, measures of infants serve as screens for early detection of risk status or for delayed development. Finally, infancy predicts important things in life like education, occupation, social mobility, and health, so knowing more about infancy is valuable.

Deconstructing infancy in the way contributes to elaborating and to explaining infancy qua a dimension of scientific inquiry, human fascination, and cultural interest. The ineffable romance of infancy may haunt us in many ways, but in other ways we now see that infancy contributes concretely to our understanding ourselves. The fact that infants are unvolitional, uncooperative, unstable, nonverbal, and motorically inept once warded off all but philosophical speculation about them. Scientists have now overcome infants' formidable and intractable posture to extract information of all sorts from and about them. We now know a great deal about babies' perceptions, thoughts, and feelings.

In modern times, a revolution has taken place in infancy studies, fueled by technological, methodological, and theoretical advances. This revolution has shown ever more faithfully how endogenous and exogenous forces coordinate to bring infants in line with their physical and social reality. Infancy is the first phase of life lived outside the womb. Characteristics developed and acquired in infancy may be fundamental to the balance of the life course; some may endure, at least in part, and they as well as others that do not, are still those which later maturation and experiences build on or modify. Infancy is only one phase in the life span, however, and so our nervous system maturity, physical development, motor capacities, perceptual abilities, cognitive competencies, idiosyncratic personalities, and social styles are also shaped by experiences and development after infancy. The start does not fix the course or outcome of development, but it clearly exerts an impact on both.

Infant and Child Mortality in Industrialized Countries

Abstract

Infant mortality is a sensitive indicator of social progress and disparities. Until the beginning of the twentieth century, the chances of surviving the period of infancy would rarely exceed 80%. General improvement in nutrition and childcare, followed by key medical discoveries and public health action, resulted in an unprecedented secular decline in infant mortality, which took place in all industrialized countries and which continues until present. Before 1950, reductions resulted mainly from management of malnutrition and infection in older infants. Mortality of newborns started to decline only after intensive development of obstetrics and neonatology in the 1960s. Nowadays, infant mortality primarily depends on the neonatal survival of high-risk babies born preterm or with low birth weight.

Infant mortality, measuring survival of newborns to their first birthday, holds a special position in demographic analysis. Shortly after birth, humans experience adaptation difficulties and are extremely vulnerable to environmental conditions. High infant mortality, very low child and juvenile mortality, and regularly increasing mortality as of age 30 are typical traits of the J-shaped curve of human age-specific mortality risk pattern. In some industrialized countries, infant mortality levels have recently fallen to historically minimal levels providing evidence that most infant deaths are preventable and avoidable. The levels of infant mortality therefore also indicate the success or failure of medicine and society. It is generally agreed that more than any other demographic indicator, infant mortality reflects the societal health and well-being progress of the population.

Level of infant mortality is prominently expressed by the infant mortality rate (IMR), defined as the number of deaths under age 1 divided by the number of live births within the given calendar year. As the number of births may strongly vary from 1 year to another, the precision of the indicator can be improved by adjusting the denominator (relating the deaths to the appropriate birth cohort or, in absence of cohort-specific data, by applying correction based on the assumption of stable share of infants from the given cohort dying during the next calendar year).

Historical and Geographic Perspective

Limited information from historical populations suggests that under natural reproduction regimes, one-third of infants would die before the first anniversary, with important surges in times of crises (war, famine, epidemics, heat waves, etc.). As the numbers of births and deaths were similar (natural growth was small), infant deaths also represented one-third of all yearly deaths. Medieval newborns were at high risk not only at the moment of delivery or during epidemics but also due to persistence of harmful feeding and childcare practices (such as swaddling, early intentional exposure to cold, early weaning, administration of raw animal milk or improper milk substitutes, use of soporifics, etc.), while overlay and smothering were also frequent. Among the poorest, infanticide was not negligible. Finally, also a death of a mother would significantly decrease the chances of a newborn to survive. Of the first-year survivors, another one-tenth or more would die before reaching the age of 5 from some of the major infectious threats (pneumonia, diphtheria, tetanus, typhoid fever, whooping cough, dysentery, smallpox, or cholera). In the earliest stages of urbanization, infant mortality in the cities was higher than that in rural areas due to higher concentration of poverty in the cities, worse housing and sanitary conditions, and lower quality of urban milk and food. In some populations, infant mortality started to decline since the beginning of the nineteenth century. General economic progress (McKeown, 1976) and spread of hygienic and childcare know-how (Preston and Haines, 1991) are believed to be the main factors thereof.

Secular Decline

The end of the nineteenth century put public health on a more rational basis. A revolution in preventive medicine occurred after discovering infectious agents of major diseases (cholera, diphtheria, typhoid fever). Etiologic advances were quickly followed by efficient treatments or vaccines, while life-saving value of pasteurizing the milk was ultimately recognized. During the twentieth century, gradual improvement of hygiene, sanitation, and nutrition, together with next medical milestones (sulfonamides in the 1930s, penicillin in the 1940s) and targeted public health campaigns including public infant milk depots (such as the *Goutte de lait* in France), further contributed to unprecedented and spectacular mortality decline. **Figure 1** provides long-term time series of IMR for five European countries. The onset of the decline varied from the earliest in Sweden to the latest in France or the Czech Republic; from the beginning of the twentieth century, however, the infant mortality decreased in all industrialized countries. The decline took place in two stages: before 1950, the trend was steep but irregular, interrupted by temporary fluctuations, while since 1950, the rates have smoothly reduced by one-third every 10 years. In the first decade of the twenty-first century, the IMR dropped below 3 deaths per 1000 live births in Finland, Japan,

Figure 1 Long-term trends in IMR (per 1000 live births). Source: Human mortality database, Czech Statistical Office.

Sweden, Iceland, Slovenia, and the Czech Republic. A 100-fold historical decline has been achieved.

Regional Disparities

As Figure 1 suggests, important disparities exist in the timing and initial levels of the secular decline. Table 1 provides an overview of IMR levels across most of the today's industrialized countries, covering – where possible – the entire twentieth century. Around 1900, infant mortality was by far the lowest in Northern Europe, with Norway being the leading country (82 deaths per 1000 live births). England and Wales, together with Finland, were the worst in this region, with levels exceeding 150 deaths per 1000 live births. In Western Europe, 150 was the minimum (in Switzerland), followed by 166 in France, 199 in Germany, and up to 216 in Austria. These historical regional disparities can be attributed to different feeding practices (breastfeeding highly prevalent in the north, while rare, e.g., in Austria), climatic conditions, and different urbanization degree (via the negative urban effect on infant mortality). In Central and Eastern Europe, with exception of Poland and Bulgaria, infant mortality exceeded 200 deaths per 1000 live births. Concerning Russia, infant mortality around 1900 could have been as high as 250 per 1000 live births, but varied from 116 to 298 depending on ethnicity and religion. High levels were explained by overall underdevelopment, while religious differentials were attributed mainly to different feeding practices (Zakharov, 1996). Due to incomplete registration of vital events in the past, the earliest rates as provided by Table 1 can be underestimated, especially in less developed countries of Southern and Eastern Europe.

Until 1950, the rate was reduced to 30 or less not only in Scandinavia, the Netherlands, and Switzerland but also outside of Europe (Australia, New Zealand, and the United States), while Austria, Belgium, France, Germany, Southern Europe, and Japan lagged behind. In the East, and especially in the Southeast, the disadvantage was much clearer – except for Slovenia, Bulgaria, Hungary, and the Czech Republic, IMRs still exceeded 100 deaths per 1000 live births.

Between 1950 and 2010, infant mortality decreased in all regions by roughly 90% regardless of initial levels. In the traditionally industrialized countries, the decrease was regularly distributed in time, and in spite of very low current levels, the relative gains have not diminished. Reaching the lowest-low levels has, however, proven particularly difficult in North America, which has led to worsening of the relative position of United States and Canada. Southern Europe was the last one to take part in the infant mortality decline, but has caught up since the 1970s. In Central Europe, the rates halved between 1950 and 1960 as a direct consequence of universal access to free-of-charge health care. Socialist health care systems were quite efficient in reducing infectious mortality, as the antibiotics and vaccines were relatively cheap, accessible, and easily controllable. Since 1960s, these systems could not keep abreast with advances in highly specialized intensive (and expensive) medicine and the progress slowed down. Eastern Europe – former European republics of the USSR and Russia – followed a segmented path with an initial decline followed by stagnation or even deterioration in the 1970s. A part of the deterioration can be attributed to the adoption of the new definition of live birth in 1974, but there has also been a real increase in infant mortality from infectious diseases in the 1970s (Meslé and Vallin, 2012). These unfavorable trends drove the Soviets to stop publishing the mortality statistics between 1974 and 1987. The infant mortality in the ex-USSR also stagnated during the posttransitional socioeconomic crisis in the 1990s and in spite of recent reduction nowadays, represents maximum with an average value of 7 infant deaths per 1000 live births.

The ranking of the countries was remarkably stable. Scandinavian countries were the leading countries in 1900 and are among the first ones in 2010. Maximum values in Albania, Moldova, and Romania have also been observed consistently.

In contrary, Austria and Germany passed from the worst to the best group. Positive reverse also occurred in some Central European countries (namely, Czech Republic and Slovenia), in Estonia, and in Japan, where the rates are now among the lowest in the world. In 1950, the range between minimum and maximum level of IMR was 105, while today it is only 11. The homogenization is, however, only apparent: when relative variability measures are used (such as coefficient of variation), the overall geographic disparities are as great as in 1950.

Components of Infant Mortality

Understanding the history and the disparities of infant mortality requires viewing it as a differentiated and irregular pathological process. A simple observation of infant deaths by time elapsed since birth shows that infant mortality is the highest shortly after the delivery. The so-called neonatal and postneonatal deaths are customarily distinguished. Neonatal mortality includes deaths occurring during the first month of

life (0–27 days) and is further decomposed into early neonatal (0–6 days) and late neonatal (7–27 days). As the infant mortality declines, deaths are increasingly concentrated to the very start of life. It is therefore recommended to additionally measure the first-day mortality (within 24 h after birth). Newborns dying in the early neonatal period are exposed to similar risk factors as the stillbirths. To aggregate this intra-uterine/intrapartum causation, and to eliminate possible effect of misclassification between live- and stillbirths, perinatal mortality rate can be computed as a sum of stillbirths and early neonatal deaths related to the sum of live- and stillbirths. Stillbirth is the delivery of a presumably viable fetus (delivery of nonviable fetus is abortion). Postneonatal mortality then encompasses deaths occurring between 28 and 364 days after birth.

Based on age at death, a method proposed in the 1950s introduced a dual pseudoetiological classification of infant deaths into endogenous and exogenous (Bourgeois-Pichat, 1951). Endogenous deaths occurring shortly after the birth are linked with congenital viability and as such are hardly preventable, while exogenous deaths occur due to failure in treatment and are – at least theoretically – fully avoidable. According to Bourgeois-Pichat, all postneonatal plus a quarter of neonatal deaths are exogenous, while virtually all first-day and most early neonatal deaths can be attributed to endogenous etiology. These estimates are no more valid for recent data, but the concept of endogenous and exogenous causes is still used.

In the nineteenth century, postneonatal component represented around two-thirds of all deaths in infancy and was a great source of mortality variation, especially between urban and rural areas or between legitimate and illegitimate children (Woods et al., 1988). Reductions in postneonatal mortality, resulting mainly from the control of malnutrition and infection, have also driven the majority of the infant mortality decline in the first half of the twentieth century. As a result, postneonatal deaths formed only one half of all infant deaths in 1950, and in the mid-1960s, their share decreased to 30% (Lantoine and Pressat, 1984). After 1960, neonatal mortality advances gained more importance due to intensive development of neonatology (Masuy-Stroobant, 1997). **Figure 2** shows the neonatal and postneonatals component of infant mortality change since the 1970s in European regions and in the United States. Neonatal mortality declined regularly everywhere as a result of better prenatal screening and prevention (e.g., prenatal ultrasound diagnostics, folic acid administration, *in utero* blood transfusion, managing high-risk pregnancies, therapeutic abortions) and intensive obstetric and neonatal health care (heart rate and acid–base balance monitoring during delivery, infant respirators, intravenous alimentation, phototherapy). The resulting progress in neonatal survival rates was so intense that it enforced changes to viability criterion (from >1000 g to > 500 g). In Eastern, Southern, and Central Europe, the neonatal mortality decline started later, but since 1970, sustained progress in both components has been observed. In North and West of Europe, postneonatal mortality stagnated between the mid-1960s and 1990s. The stagnation has been explained as a consequence of postponing neonatal deaths to the post-neonatal period, and the emergence of the sudden infant death syndrome (SIDS) as the leading postneonatal cause of death in developed world (Barbieri, 1998). Since 1990, the progress was resumed, dividing the postneonatal mortality by three in the following two decades. In the United States, the decline of both components was slower than in the North and the West of Europe and has virtually stopped since 2000. Several explanations have been put forward, among them higher registration of very preterm and very low birth weight newborns as live births (applying pragmatic rather than definition-based criterion of live birth), but most of the

Figure 2 Components of infant mortality change since 1970, per 1000 live births. Regions of Europe and the United States. Note: due to unavailability of data prior to 1990, Albania is not included in the data set. Source: World Health Organization, National Center for Health Statistics.

observed stagnation is due to higher occurrence and lack of survival progress of high-risk newborns (MacDorman and Mathews, 2008).

Table 2 shows the components of infant mortality in 2006. Early neonatal deaths represent the largest infant mortality component, reflecting extreme frailty of newborns on one side and the quality and availability of neonatal health care on the other side. Countries with lowest IMRs usually have the lowest neonatal rates (Sweden, Finland, Spain, Greece, France, Czech Republic, Slovenia, and Estonia). Neonatal mortality is considerably higher in most former socialist countries, and also in Denmark, the Netherlands, Switzerland, the United Kingdom, and the United States. Diverse registration practices (pragmatic, birth weight/gestational age criterion, or with additional condition of a minimum survival time) are at source of some part of the observed disparities in early neonatal mortality, most sensitive to distinction between live- and stillbirths (Gourbin and Masuy-Stroobant, 1995; Mohangoo et al., 2011). The shares of postneonatal deaths are currently under 30% in countries with lowest IMRs (less than 4), and close to 40% in countries with highest IMR levels. High post-neonatal mortality in the United States (2.2 per 1000 live births), unrelated to the differences in perinatal registration, points to the relative deterioration of infant health.

Medical Causes of Death

The World Health Organization (WHO) international classification of diseases devotes two separate chapters to conditions of infancy, entitled 'Certain Conditions Originating in the Perinatal Period' (XVI) and 'Congenital Malformations, Deformations and Chromosomal Abnormalities' (XVII). One of the earliest available cause-of-death statistics show that 40–50 infant deaths per 1000 live births in France in 1930 out of 80–100 in total was caused by perinatal and congenital disorders, while an equal share of deaths were due to infectious diseases (Vallin and Meslé, 1988). In the Czech Republic in 1920, out of 169 infant deaths per 1000 live births in total, 95 were due to infections diseases, while 50 (similar as in France) were diagnosed as due to congenital weakness or preterm birth complications. Nowadays, 75% or more of all infant deaths are due to perinatal and congenital causes. Due to extended survival of high-risk infants, both perinatal and congenital causes of death are becoming an important component of postneonatal and child mortality.

Figure 3 shows the trends in IMRs for main groups of causes of death per 100 000 live births in France since 1950. For the

Figure 3 Causes of infant mortality in France since 1950, per 1000 live births. Source: Reconstructed time series of causes of death (Vallin, J., Meslé, F., 1988. Les causes de décès en France de 1925 à 1978. Presses Universitaires de France, Paris).

whole period, perinatal causes of death (typically hypoxia, asphyxia, birth trauma, hemorrhage, and prematurity) were the main cause of infant deaths but declined rapidly. On the contrary, congenital anomalies underwent much slower decline and are now the second leading cause of infant deaths. Deaths from infectious diseases, as well as from other diseases (where pneumonia and gastroenteritis are prominent), became rare. Due to better protection and care, and owing to numerous safety measures and products, accidental mortality has declined since the mid-1970s. In France as in many industrialized countries, an increase in SIDS, formerly called crib or cot death, a diagnostic category gathering sudden deaths in infancy where the initial cause of death remains unknown even after thorough investigation and autopsy, was observed in the 1970s. Deaths from SIDS peak between the second and the fourth month of life and are more likely to occur in boys and in infants sleeping on the belly or on the side. Among alleged risk factors (such as the mother's age, maternal smoking, or preterm birth), sleeping position was targeted by public health 'Back to sleep' campaigns, resulting in rapid decrease of the SIDS incidence (Barbieri, 1998). SIDS, together with congenital malformations and infection, remains the leading cause of postneonatal mortality in most low-mortality countries. Similar analysis for Ukraine for the period 1965–2006 (Meslé and Vallin, 2012) has shown virtually no improvement in perinatal and congenital causes of death, and even an increase in injury and poisoning. Only postneonatal causes (infectious and respiratory diseases) have declined since the 1980s, pointing to large reserves in the health care system in the ex-USSR countries.

Factors of Infant Mortality

Infant mortality is a highly stratified, multivariate, and multilevel process. As infant death prevention was among the first public health target, its risk factors have received long-term attention. Initially, two main determinants were identified: nutritional status (of the mother and the child) and cleanliness of the environment. Today, a variety of factors affecting infant mortality are identified and customarily classified as biological, socioeconomic, and environmental:

1. Environmental factors include national or local level of economic development, medical awareness, access to health care, access to education, climatic conditions, and air pollution.
2. Socioeconomic factors are measured by the position of the household (individual indicators of education, occupation, income, marital status) or by area-based indicators of deprivation. In research of a general theory of infant mortality decline, mother's educational status is believed to play central role (Masuy-Stroobant, 2002);
3. Biologic factors encompass individual characteristics on the mother's and the child's side (gestation length, birth weight, sex, race, birth order, birth interval, multiple birth, mother's age, genetic predisposition, maternal stress, nutrition status, etc.).

Because of a great deal of interaction, it is impossible to clearly distinguish the separate effect of each factor. For example, social disadvantage, independent of its measure, increases both the risk of infant death and that of preterm or low birth weight delivery (Weightman et al., 2012). Typically, the factors operate in a multiplicative sequence: socioeconomic deprivation would increase the risk of maternal smoking and/or poor nutritional status, which is associated with higher risk of low birth weight or preterm birth, which multiplies the risk of infant death. Birth weight and gestational age – indicators of intrauterine development – are now the strongest predictors of neonatal and infant survival. Births before 37 weeks of gestation are classified as preterm (as very preterm before 32 weeks), while the accepted dividing line for low birth weight is 2500 g and 1500 g for very low birth weight. The neonatal mortality regularly increases both with lower and the higher-than-average birth weight, and this pattern remains unchanged in spite of large recent reductions (Wilcox, 2001). Gestational-age-specific mortality data are scarcer than birth-weight-specific data, but follow similar gradient of increasing risk with shorter gestation duration (Mohangoo et al., 2011). The resulting IMRs are thus affected by (1) survival of low birth weight and preterm babies and (2) the share of these high-risk newborns in the population. The latter increases in many industrialized countries due to more frequent multiple births, postponement of childbearing, increase in delivery management techniques (induced labors, Cesarean sections), and worsening of social disparities. Lowest shares of low birth weight neonates (under 5%) are currently found in Scandinavian countries, while in Hungary, Portugal, Spain, Greece, Bulgaria, United States, and Japan, the proportions exceed 8% (OECD, 2011). Low birth weight babies have about 20 times higher infant mortality than heavier ones (Wilcox, 2001). The survival of low birth weight neonates has, however, significantly improved: in the United States, a drop from 694 to 422 deaths per 1000 live births was observed for the very low birth weight category (500–1499 g) and from 94 to 36 for low birth weight category (1500–2499 g) between 1960 and 1980 (Buehler et al., 1987). Important country-specific differences in low birth weight survival exist between Central and Eastern Europe and between Western countries, especially for very low birth weight and very preterm births (Rychtaříková, 1999; Masuy-Stroobant, 2002; Mohangoo et al., 2011). The birth-weight-specific neonatal mortality rate nowadays ranges from 0.5 deaths per 1000 live births for the best-performing category (3500–3999) to approximately 400 deaths per 1000 live births for the first 'viable' category (500–749 g) (based on the US data, Alexander et al., 2003). Birth weight also predicts mortality at different gestational age: thus, even in perfectly term births (40–41 weeks of gestational age), mortality risk is considerably higher for low birth weight babies. This disproportion has been attributed to the intrauterine growth restriction syndrome. Lowest neonatal mortality rates are often found for low birth weight babies in disadvantaged populations, which is known as the low birth weight paradox. The paradox has been observed in small babies of smokers, African-Americans, or less educated and single women (MacMahon et al., 1965; Yerushalmy, 1971; Syrovátka and Rychtaříková, 1984; Wilcox and Russel, 1990). The existence of the paradox stresses the importance of distinction between birth weight and gestational age: among low birth weight babies, only the small and preterm ones are at highest mortality risk (Wilcox, 2001). As preterm births are now responsible for up to two-thirds of all infant deaths (based on US data, MacDorman and Mathews, 2008), preventing

spontaneous preterm birth and intrauterine growth retardation, together with reducing of social inequalities, is a necessary condition for further infant mortality decline.

Less significant biological factors include sex of the child (consistently higher risk of infant death in males), age of the mother (J-shaped risk pattern with lowest risk in the mid-childbearing age), birth order (associated with higher death risk especially if at inappropriate age, e.g., third child at age 20–24 Rychtaříková, 1999), and multiple birth (positively correlated with both low birth weight/prematurity and death risk). The biosocial stratification of infant mortality follows a similar pattern in all industrialized countries, but is generally stronger in Central and Eastern Europe than in traditionally industrialized countries.

Child Mortality

In worldwide concepts such as the WHO development strategies, child mortality is usually expressed as the probability of dying under age 5 years (the so-called under-5 mortality rate). In demographic terminology, child mortality refers only to the period between the first and the fifth birthday and as such is measured by the (postinfantile) child mortality rate: the sum of all deaths at age 1–4 years related to the average number of children alive within the same interval. During the eighteenth and the nineteenth centuries, child mortality rate was approximately five times lower than IMR. The twentieth-century victory over infectious diseases resulted in more pronounced drop in child mortality compared to infant mortality and resulted in an increase of this ratio. In 1950, lowest child mortality (less than 2 deaths per 1000 alive) was found in Nordic countries, Austria, Switzerland, the United States, and Canada. Highest values were observed in Portugal (13), Japan (10), Spain (7), or Bulgaria (8). Nowadays, child mortality is as low as 0.15 deaths per 1000 alive in the Nordic countries; 0.2 deaths per 1000 alive in Western and Central Europe, Canada, and Japan; 0.3 deaths per 1000 alive in the Baltic countries and in the United States; and 0.5 deaths per 1000 alive in Ukraine and Russia. Main causes of child death are nontraffic accidents (mainly accidental drowning and falls), diseases of infancy (perinatal and congenital), cancer, and road accidents. All these causes have regularly decreased since the 1960s due to better protection, prevention, and health care provided to increasingly precious children. Similar to infant mortality, socioeconomic differentials are observed in child mortality. As the health status between conception and 5 years sets the human capital in later life, reducing inequalities in infant and child health would help to equalize health status through the remaining life course.

Infant and Child Mortality in the Less Developed World

Magali Barbieri, Institut National d'Études Démographiques, Paris, France

© 2015 Elsevier Ltd. All rights reserved.

Abstract

About 7 million children below 5 years of age die every year around the world. The situation is particularly dire in sub-Saharan Africa where infant and child mortality rates are 15 times higher than in high-income regions. Over two-thirds of all child deaths are attributable to a small number of infectious and parasitic diseases aggravated by malnutrition, and most could be avoided with the mass implementation of simple and low-cost interventions. Government commitment along with the support of international organizations has led to tremendous improvements over the past few decades; however, in the poorest countries, the challenges of AIDS and the resurgence of diseases such as malaria and cholera have slowed the positive trends observed since the 1950s.

In 2014, about 7 million children below 5 years of age will die around the world. Of which, 3.4 million deaths will occur in sub-Saharan Africa, 2.3 million in South Asia, and fewer than 100 000 in the developed world. Globally, this death toll represents more than one child death every 5s. The vast majority of these children die from diseases preventable or treatable with simple and low-cost medical techniques. Despite this depressing toll, tremendous progress has been achieved since the 1950s. Worldwide, the proportion of children dying below 5 years of age declined from about 200 per 1000 births around 1950 to 120 per 1000 in 1980–85, and further to about 55 per 1000 in 2005–10. Compared to the conditions of the 1950s, improvements in health care and sanitation have resulted in the survival of nearly 20 million children who would have died every year.

Mortality Measures

Numbers of child deaths are rough estimates rather than exact measures because accurate data on child health and mortality in developing countries are not easy to attain. The gold standard in estimating the level of child mortality is to compute the ratio of the number of deaths in a given year to the number of births reported to the vital statistics system. However, only one-quarter of the world's population lives in countries with complete vital registration, and these are countries with the lowest mortality. To circumvent this problem, major data collection efforts have been undertaken since the 1980s and techniques for estimating child mortality have improved so remarkably that it is now possible to make reliable comparisons among all the world's regions and to better understand disease processes in developing countries.

In countries where vital registration data are incomplete or unreliable, nationally representative household surveys constitute the main source of statistical information. Starting in the 1970s, international programs, such as the World Fertility Surveys and the Demographic and Health Surveys funded by the United States Agency for International Development, have become the main sources of such data. More recently, a complementary program of data collection, the Multiple Indicator Surveys, has been developed by UNICEF to monitor progress toward the Millenium Development Goals. These surveys often provide birth history data that can easily translate into estimates of child mortality.

The Millenium Development Goals are eight major development targets established during a United Nations sponsored summit of government leaders in 2000 to improve the conditions of life of the most economically deprived populations around the world. The fourth of these goals is to reduce the mortality of children under 5 years of age by two-thirds by 2015 compared to 1990. Two measures are traditionally used by demographers to characterize child mortality: the infant mortality rate and the under-five mortality rate. The infant mortality rate is the ratio of deaths below 1 year of age during a given calendar year to the number of live births during that same calendar year. The under-five mortality rate is the proportion of children who die before reaching their fifth birthday in a 1-year cohort of live births. Both rates are usually provided per 1000 births.

Geographic Disparities

The mortality of young children has declined everywhere around the world; however, the favorable trend observed at the regional level conceals a wide diversity of situations (Figure 1). About half of the 50 least developed countries still experience an under-five mortality rate above 100 per 1000 and differences between regions and among countries in each continent continue to widen.

Latin America was the first developing region to benefit from medical progress. Among developing regions, the decline in child mortality in Latin America is more uniform than in Asia or Africa. Improvements in child mortality began in the early decades of the twentieth century and have been steady since. Currently, the overall probability of dying below five is around 20 per 1000. Even the poorest countries (namely Haiti, Bolivia, and Honduras) exhibit child death rates well below 100 per 1000, and in many countries children's survival chances are now close to those observed in Europe or North America. This is particularly true in the Caribbean where under-five mortality rates around 10 per 1000 are not uncommon.

Asia exhibits the largest internal diversity. Overall the average probability of dying below five is now less than 45 per 1000 – but it is three times higher in South Asia than in East

Figure 1 Under-five mortality rate in 2011. Source: Map produced by the author using the R worldmap package (A. South, 2013) and data in Level and Trends in Child Mortality. Report 2011. Estimates developed by the UN Inter-agency Group for Child Mortality Estimation (UNICEF, WHO, World Bank, UN DESA, UNDP).

Asia. Variations are even wider among countries within the same continental subregion. For example, the infant mortality rate reaches 75 and 72 per 1000 in Yemen and Pakistan, respectively, more than 15 times the level recorded in Cyprus and Israel. Similarly, in Southeast Asia, it is over 40 per 1000 in Laos and Cambodia, compared to less than 5 in Japan and in the Republic of Korea. The overall level of mortality in Asia is largely driven by the two most populated countries of the planet, China and India, which experience rates of infant mortality of 13 and 47 per 1000, respectively, and an under-five mortality of 15 and 60 per 1000. Nearly a quarter of all deaths under 5 years of age, or a total of 1.7 million, occurs in India because of the country's size and its relatively high level of child mortality.

Africa remains by far the region with the highest overall level of infant and child mortality. One in 15 children dies during his/her first year and one in 10 before reaching his/her fifth birthday. Wide disparities are observed between Northern and Southern Africa, on the one hand, and Western, Central, and Eastern Africa on the other. In Northern and Southern Africa, the under-five mortality rate is around 30–40 per 1000 while it is above 80 per 1000 in nearly every African country outside of these two regions. Several of these countries exhibit extremely high levels of under-five mortality: in Angola, the Central African Republic, Chad, the Democratic Republic of Congo, Guinea-Bissau, Mali, Sierra Leone, and Somalia, more than 15% of all children die before their fifth birthday. Even there however, survival has improved, with a decline in the under-five mortality rate on the order of 25% over the past 15 years or so.

Intraregional disparities are more the result of diverging trends over time than variations in the initial levels of mortality. Indeed, historical research suggests that the infant mortality rate was well above 200 per 1000 in preindustrial Europe as well as in developing countries prior to the twentieth century. By 1950, in contrast to Asia and Africa, Latin America had achieved an average level of mortality significantly below the pretransitional level. During the following decades, while mortality continued to decline steadily in Latin America, the other two main continents of the developing world experienced sharp drops in infant and child mortality (Figure 2), with the decline in Asia during 1955–75 being especially marked.

While both regions exhibited similar levels of infant mortality around 1950 (about 180 per 1000), the proportion of children dying during their first year fell by 40% in Asia (from 160 to 100 per 1000) in 20 years, a remarkable achievement largely credited to substantial improvements in China. During the same period, the proportional decline was about 30% in Latin America and 25% in Africa.

Medical Causes of Infant and Child Deaths

As socioeconomic development proceeds, countries move through the epidemiological transition. The concept was coined by Omran (1971) to describe the shift in disease composition from infectious and parasitic diseases to congenital and degenerative diseases. This trend parallels a change in the age structure of mortality, with an increase in the average age at death. More than 60% of all deaths are experienced by children below 5 years of age in high-mortality populations compared with 3% in industrialized nations. As the level of mortality declines, deaths tend to concentrate increasingly in the months, weeks, and days immediately after birth.

The Rising Share of Neonatal Mortality

Neonatal mortality, which refers to mortality during the first 4 weeks of life, now represents over 40% of the overall mortality of children under 5 years of age worldwide. A quarter to half of these early deaths takes place within 24h of delivery. They are mostly attributed to intrapartum conditions, especially the complications of prematurity and low birth-weight (for about one-third of them) as well as birth asphyxia (for another 23%), and to infectious diseases (35%), sepsis,

Figure 2 Infant mortality rate by region: 1950–55 to 2005–10. Source: World Population Prospect 2010, United Nation Population Division, 2011.

meningitis, pneumonia, tetanus, and diarrhea in particular (Lawn et al., 2006). The vast majority of neonatal deaths could be prevented without intensive care, through the implementation of low-technology interventions such as prenatal checkups and maternal immunization, hygienic practices during birth, thermal care, treatment for infections, and breastfeeding support. Because these measures must be taken sequentially, before, during, and after delivery, they have been promoted through the concept of a continuum of care. Continuity in care is more costly than most of the interventions directed at older children though, since a more sustainable health system with a larger workforce is required, but this approach would also avert part of the nearly 3 million stillbirths and a large proportion of the 290 000 maternal deaths occurring every year. Because progress has been slower for neonatal than for postneonatal and early childhood mortality, the proportion of child deaths occurring during the first weeks of life is higher where the overall level of under-five mortality is lower, from about 55% in some regions of Asia (Western Pacific in particular) to less than 25% in Africa, and neonatal conditions now represent the leading cause of death among all children worldwide.

The Predominance of Infectious and Parasitic Diseases

After the first month of life, deaths are predominantly attributed to infectious and parasitic diseases. Over 60% are due to only three diseases or disease categories (Johnson et al., 2010; Liu et al., 2012). The highest toll is caused by acute respiratory infections (Williams et al., 2002). Pneumonia alone directly results in 1 million deaths of children between 1 and 60 months of age in developing regions. Pneumonia is also believed to indirectly contribute to an additional 2 million child deaths for which another underlying cause is reported. It is particularly deadly in South and Southeast Asia with more than 30% of all child deaths due to this cause in some areas. Diarrheal diseases are the second leading cause in less developed regions, with almost one in five of all child deaths. Malaria continues to kill more than half a million children every year. It is the leading cause of mortality among children in Africa (Rowe et al., 2006). The other main causes of child death are external causes (injury), meningitis, AIDS, and measles. Most of these diseases also represent a high proportion of morbidity in industrialized countries. They are, however, much less lethal there because of differences in the immune system of children born in these countries: malnutrition is a major factor in the weakening of natural resistance, while immunizations are fundamental to the building of artificial resistance.

The Role of Malnutrition

The major role of nutrition in child mortality processes is now well documented. The effect of malnutrition on mortality was overlooked for a long time because malnutrition is rarely the direct cause of death. Fewer than 200 000 deaths of children below 5 years of age are attributed to either marasmus or kwashiorkor, the most acute forms of malnutrition. However, recent research has demonstrated that malnutrition is an initial or aggravating factor in one-third to half of all child deaths. Malnutrition is usually the result of a combination of inadequate dietary intake and infection. It affects over one-quarter of all the children under 5 years of age in the developing world.

There exist different kinds of malnutrition. Malnutrition not only results from a deficiency of protein and calories but also from a lack of vital dietary minerals and vitamins. International organizations single out deficiencies of four micronutrients (iron, iodine, vitamin A, and zinc) as being particularly common and of special concern for children in developing countries. The general effect of malnutrition is to lower the defenses in children's immune systems, resulting in a greater incidence, severity, and duration of common childhood diseases. Vitamin A deficiency makes children especially vulnerable to infections and worsens the course of many infectious diseases. Death rates in children lacking vitamin A are 20–30% higher than in other children. Vitamin A deficiency has been shown more particularly to reduce children's resistance to diarrhea and measles. Not only does malnutrition increase the probability of infectious and parasitic diseases, but

diseases also speed nutrient loss and suppress appetite, provoking a vicious circle ultimately leading to death. For instance, in parts of Africa where malaria is common, studies show that about one-third of the cases of child malnutrition are caused by malaria.

In an attempt to reduce the incidence of malnutrition in the earlier months of life, international organizations such as the WHO and UNICEF have been actively promoting breastfeeding. Though breastfeeding durations had declined significantly during the 1980s and early 1990s due to the combined effects of commercial pressure for the use of formula and the increased participation of women in the labor force, such efforts have proved useful in encouraging breastfeeding in the poorest countries and the proportion of newborns exclusively breastfed has increased in a number of countries over the past decade or two (Cai et al., 2012). Breastmilk contains all the nutrients, antibodies, hormones, and antioxidants an infant needs to thrive during the first 6 months of life. Breastfed children not only show better immune responses to immunizations, but they also exhibit natural resistance against a number of infectious diseases, gastrointestinal and respiratory in particular. By comparison, commercial infant formulas are an expensive and inferior substitute for breastfeeding. They are frequently overdiluted in order to save money and mixed with unsafe water before being fed to children in unsterilized bottles capped with unclean nipples. Research indicates that in countries where infant mortality rates are high or moderately high, a bottle-fed baby in a poor community is 14 times more likely to die from diarrheal diseases and 4 times more likely to die from pneumonia than a baby who is exclusively breastfed. Unfortunately, only one in three infants below 6 months of age is currently in the latter situation.

Devastating Epidemics

Old curses have recently intensified. Epidemics of plague and upsurges in cholera have demonstrated a surprising rebound in parts of Africa, Asia, and Latin America. Malaria has also showed frustrating resistance to the many approaches tried to combat the disease. The parasite is no longer vulnerable to some of the most powerful antimalarial compounds available. For a time, the widespread use of pesticides reduced the incidence of the anopheles mosquito transmitting the parasite, but it, too, has developed resistance.

In addition to such historically deadly diseases, AIDS has become a major killer of young children in parts of the developing world and it is now the sixth leading cause of child deaths worldwide (UNAIDS, 2012). The AIDS epidemic is a main public health issue in Africa and in parts of Asia, threatening millions of children with premature death. Its real impact is very difficult to measure because of a lack of statistical data and problems of diagnosis in the countries most affected by the epidemic. The burden of the disease has been steadily increasing for children over the 1980s and 1990s but appears to have decreased since. According to recent estimates from the Joint United Nations Program on HIV/AIDS (UNAIDS, 2012) and WHO, about 200 000 children below 15 years of age are now dying every year from the disease, compared to 500 000 children 15 years ago. The number of newly infected children, 90% of them born in sub-Saharan Africa, is estimated as 330 000 in 2011. This is however less than half the number in 2003. The number of new infections has declined everywhere but in Angola, Congo, Equatorial Guinea, and Guinea-Bissau. The majority of infected children have acquired the infection directly from their mothers. Mother-to-child transmission of HIV, also known as vertical transmission, occurs during pregnancy, during labor and delivery, and through breastfeeding. Research has showed that a child stands the greatest risk of vertical transmission (about 20%) at the end of the pregnancy and during labor. There is an additional 15% risk that an infant will become infected through breastmilk. Consequently, more than one in three of the babies born to mothers infected with HIV stand at risk of infection. The vast majority of those infected die before the 5 years of age (Sutcliffe et al., 2008). The cumulative number of children infected with HIV/AIDS had reached more than 6 million by the end of the twentieth century, and the mortality of young children had been increasing up to 50% in countries most affected by the epidemic, mainly located in Eastern and Southern Africa such as Namibia or South Africa. In Zimbabwe, AIDS was the biggest single killer of the nation's children under 5 years of age at the turn of the twenty-first century. Because of the very slow changes in sexual behavior and the difficulty of developing an effective vaccine, prevention of mother-to-child transmission through measures such as artificial infant feeding rather than breastfeeding as well as the increasing use of antiretroviral drugs have played an essential role in lowering the incidence of the disease among children and increasing the survival odds of those who become infected. Though nearly 6 in 10 pregnant women infected with HIV are now receiving antiretroviral prophylaxis in sub-Saharan Africa, not all subregions are doing well and transmission rates still reach about 30% in Central and Western Africa (UNAIDS, 2012).

HIV/AIDS remains a substantial burden in countries with poor health care systems. AIDS is an expensive disease. In communities with limited resources, the epidemic diverts a tremendous proportion of the available budget away from basic health care toward intensive care. In countries with mature epidemics, such as Uganda, Zambia, and Zimbabwe, some doctors report that up to three-quarters of the beds in hospital pediatric wards have at times been occupied by children ill from AIDS. Another indirect effect of the epidemic is the dramatic increase in orphanhood. Since the beginning of the epidemics, nearly 16 million children have been orphaned because of the disease, more than 95% of them in sub-Saharan Africa, and the survival odds of orphan children are significantly lower than those of others. Efforts will need to expand quickly for the UNICEF goal of zero new child infection by 2015 to be achieved.

Economic Determinants

Poverty is viewed as the underlying factor for high child mortality in developing countries. At the family level, economic privation clearly affects the health of children. Low purchasing power is related to poorer nutrition, the lack of

ready access to a safe water supply and proper sanitation, and unhygienic conditions in and around homes. Such conditions are typically associated with a high prevalence of childhood diarrhea and they have significant implications for the spread of infectious and parasitic diseases.

However, at the national level, the relationship between national income and infant and child mortality is much less systematic. Wealthier countries are clearly those in which children are less likely to die. As indicated in Figure 3, countries with a GNP per capita above $5000 have a level of infant mortality below 25 per 1000 and this has changed very little over the past three decades.

Nonetheless, the relationship does not appear to be determinative since countries faring the worst in terms of health and mortality are not always the poorest. There is a wide range of situations among poor countries with similar levels of national income per capita. For example, while GNP per capita in Indonesia is more than twice than in Vietnam ($3500 vs $1400), infant mortality is lower in the latter (at 17 per 1000 compared with 25 per 1000 in Indonesia). The contrast is even more striking in sub-Saharan Africa where the ratio of infant mortality reaches three to one in countries with the same level of GNP per capita ($500–550), such as Rwanda or Madagascar on the one hand (at 50 and 60 per 1000, respectively), and the Central African Republic on the other (at over 160 per 1000). Equatorial Guinea is an extreme case with a GDP per capita higher than that of Portugal and Greece and close to that of Spain and Italy thanks to its oil exports, but a level of under-five mortality that is among the highest in the world, with nearly 12% of children dying before reaching their fifth birthday. Poverty per se is thus insufficient to explain geographic variations in infant and child mortality across the world and other factors must be taken into account.

Political Commitment

Experience and research demonstrate that without a commitment at the government level the health of children improves very slowly. Poor countries experiencing a low level of mortality relative to their level of socioeconomic development are those where a primary health care strategy was adopted early and implemented steadily at the national level, following recommendations first developed at the 1978 WHO conference in Alma-Ata. The strategy recommended direct medical intervention (such as immunizations and oral rehydration therapy), nutrition programs, and activities indirectly affecting health, such as hygiene, education, and family planning campaigns. China, Cuba, Vietnam, and Costa Rica are well-known examples of poor countries where the primary health care strategy has been successfully implemented. Even countries that have not been able to implement the strategy as a whole but only in part have benefited from a decline in child mortality. Among the main achievements of the strategy are the declines recorded over the past decade in the mortality attributable to pneumonia (−22%), diarrhea (−18%), and measles (−18%) due to low-cost interventions like the distribution of antibiotics, oral rehydration salts and zinc and immunization, as well as better hygiene practices, improved water and sanitation facilities, and adequate nutrition, including exclusive breastfeeding for children below 6 months of age.

In many regions of the world, the international community has played an important role in promoting primary health care services. WHO, UNICEF, and many other public or private organizations have worked with governments toward the goal of immunizing the world's children against six preventable diseases. Due to very active campaigns carried out during the 1980s, rates of child immunization against measles, tetanus, poliomyelitis, tuberculosis, pertussis (whooping cough), and

Figure 3 Relationship between the probability of dying below five and national income per capita in 1981 and in 2011. Source: For the under-five mortality rate, Level and Trends in Child Mortality. diphtheria have risen from about 10% in the mid-1970s to 30% 10 years later and 80% around 1990. The proportion of children vaccinated leveled out over the 1990s but increased again after 2000 and immunization rates against the main six targeted diseases now reach 85 to 90% overall (75–85% in sub-Saharan Africa). This achievement has meant the prevention of up to 3 million child deaths a year (http://www.who.int/gho/immunization/en/index.html, consulted 6 January 2014).

In conclusion, dramatic progress has been accomplished since the 1970s, so that children in many Asian and Latin American countries do not experience a higher risk of dying than those born in industrialized regions. There remain sources of serious concern for the future of child health in the most deprived areas of the Third World, however, and inequalities continue to increase among subgroups of national populations and among countries. As of 2012, only half of the world developing regions and 15 of the 66 countries with over 40 under-five deaths per 1000 live births are on track to achieve this Millenium Development Goal for 2015 (UNICEF et al., 2012). The challenge is to circumvent economic and political difficulties in order to implement the health interventions known to accelerate the reduction of infant and child mortality.

Infant Gaze Behaviors

Rechele Brooks, Institute of Learning & Brain Sciences, University of Washington, Seattle, WA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The perception of eye gaze is a crucial component of social understanding from infancy to adulthood. Individuals can use eye gaze as a nonverbal means to communicate interests, intentions, and other mental states. Gaze behaviors increase in complexity with development. This article reviews the emergence of four gaze behaviors: visual scanning, gaze cueing, alternating gaze, and gaze following. A deep understanding of infants' gaze behaviors has implications for language, autism spectrum disorders, robotics, and theory of mind.

Although many human social interchanges occur via mobile phones and other technologies, communication in person is still a key context for social interaction. In face-to-face conversations, perception of eye gaze is a crucial factor in social understanding. By using eye gaze, individuals can convey that they are attracted to a person, reveal that they are lying, or indicate that they have completed their conversational turn (Kleinke, 1986). In short, gaze behaviors serve many functions in social exchanges.

Eye gaze is both an entry point for understanding other people's minds and a way to determine what information is relevant in the environment. From the adult view, eye gaze is an essential component to understanding a person's mental states, including emotions and intentions. However, a person's eye gaze can also refer to something in the external world. For example, if a person looks up into the sky, onlookers follow his or her gaze. The gaze followers want to look at what that person sees above them. Adults realize that people are in visual contact with objects and obtain information by looking at them. The developmental question is when does a psychological understanding of eye gaze emerge.

Theoretical Background

Infants' abilities to make inferences about people's mental states – including perception, emotion, and beliefs – remain intensely debated (Flavell, 2004; Metcalfe and Terrace, 2013). This debate extends into the interpretations of infants' gaze behavior. Though infant acts often appear outwardly the same as adult ones, these actions may have different underlying meanings. On one side of the debate, theorists argue eye gaze already has psychological meaning to young infants (e.g., Baron-Cohen, 1995). On the opposing side, others suggest that infants' gaze behaviors reflect simpler mechanisms based on behavioral explanations, such as noticing contingencies between head/eye orientation and external objects (e.g., Moore, 2008). However, we should consider a third perspective (Brooks and Meltzoff, 2002): Infants' understanding of gaze may change. Infants gradually come to understand the psychological nature of eye gaze.

Gaze behaviors have implications for development, because they can advance infant cognitive and social learning. When infants follow the gaze of others, infants can learn about desires, emotions, and perceptions of others, as well as identifying significant information in their surroundings. When infants alternate their gaze to and from an object, they have a nonverbal means to initiate and maintain social interactions. The importance of these actions is highlighted by the fact that many gaze behaviors are impaired in children with autism spectrum disorders (ASD) (Baron-Cohen, 1995; Toth et al., 2006). Other research has established that gaze following predicts subsequent language acquisition for children with typical development and atypical development (Brooks and Meltzoff, 2008; Kasari et al., 2008; Mundy et al., 2007), in part because this ability enables the child to coordinate what a person is looking at with what he or she is labeling.

Current Knowledge

There are at least four distinct gaze behaviors that are widely studied: visual scanning, gaze cueing, alternating gaze, and gaze following. These gaze behaviors are reviewed in order of complexity and with attention to their functional significance. Developmental changes in gaze following will be used to discuss infants' emerging understanding of eye gaze.

Visual Scanning of the Face

Neonates scan the eye region of the face (Johnson et al., 2008). They prefer to look at faces with eyes oriented forward rather than ones with eyes averted to the side. By 2 months of age, infants fixate on the eyes more than the mouth; declines in scanning the eyes by 6 months of age predict developmental outcomes for children at risk for autism (Jones and Klin, 2013). These early scanning patterns may reflect an automatic reaction to eyes, which may lay the foundation for understanding mutual gaze. However, detecting eye gaze may rely on the physical properties of the display, such as the direction of high-contrast spots. As a minimum definition, visual scanning of the face simply requires that infants look at facelike stimuli.

Gaze Cueing

Gaze cueing refers to when infants shift their own gaze after being cued by a centrally positioned stimulus, such as a face with averted eyes. In the typical gaze-cueing paradigm, a screen

displays a digitized human face with eyes that shift laterally before a target becomes visible on the left or the right of the screen (Hood et al., 1998). The experimental manipulation is whether the eyes move to the same side as the upcoming target ('cued' target trials) or whether the eyes move to the opposite side ('uncued' target trials). In most studies, the face disappears before the onset of the targets. The results show that infants and adults have a faster response to the cued than the uncued targets (Johnson et al., 2008). For example, infants look faster to the left target after the eyes shift to the left. This effect is even found with newborns who are shown simplified, schematic faces.

However, there are reasons to suggest gaze-cueing responses are different than following the gaze of actual people. First, the cueing effect is disrupted when the face (and eyes) remains visible on the screen (Hood et al., 1998). Second, presenting high-contrast black spots (instead of eyes) results in a similar cueing effect for newborns (Johnson et al., 2008). Third, the timing of newborns' and young infants' gaze shifts to the target suggests that they are automatically, rapidly processing the central cue. Finally, infants' target looks could occur because of displayed motion. When they respond to the apparent movement, they need to only slightly shift their gaze to the materializing targets. This is in direct contrast to live interactions. When a mother looks at an object, her face does not disappear; nor do objects suddenly appear immediately near her face. Thus, these gaze-cueing responses could be explained by different mechanisms than those that underlie intentionally following a person's gaze. As a minimum definition of cueing, infants shift their own gaze in response to a lateral shift of spots.

Alternating Gaze

When infants look at an object and then make eye contact with their parents, infants are 'alternating gaze.' Instances of this gaze shift behavior may occur during play when infants look up from their toy to their parent's face. Infants typically begin to use gaze in this manner by 9 months of age.

The likelihood that infants will engage in alternating gaze varies with the social context. When infants are already facing an adult tester and a toy, 9-month-olds alternate their gaze from an object to the adult's eyes as often as 18-month-olds do (Mundy et al., 2007). In contrast, during unstructured play with their parents, 9-month-old infants briefly and rarely initiate this behavior even though they are playing near their parent (Carpenter et al., 1998). Infants' gaze alternation significantly increases with age during naturalistic play. By 18 months, infants more frequently shift their eye contact from an object to a person, but they still spend less than half of their unstructured play during periods of alternating gaze (Adamson et al., 2004). In both contexts, alternating gaze can serve a similar function of showing interest in their social partner and an object. The use of alternating gaze also occurs when infants face an unfamiliar, ambiguous object. When infants alternate their gaze in this context, they are said to be 'social referencing' (*see* Social Referencing during Infancy and Early Childhood across Cultures). After looking to their parent (or other adult), infants regulate their own behavior, such as by modifying their approach toward the ambiguous object.

From the adult perspective, eye gaze creates a psychological connection between social partners and an object. Infants may alternate their gaze to indicate or refer to an object. To find evidence of infants' understanding, researchers examine whether infants *initiate* eye contact with their social partner after looking at an object (Carpenter et al., 1998; Mundy et al., 2007). In this manner, infants' gaze helps them to establish an object as a topic of conversation. They can use their own gaze to 'show' an object to their parent, who in response may comment on it. However, when making eye contact, infants may be simply checking what their parent is doing (Moore, 2008). Infants may look at their parent's face out of habit, based on an established social routine without awareness of shared visual attention. As a minimum definition of alternating gaze, infants disengage their attention from an object and shift their gaze to a person's eyes.

Gaze Following

The prototypical example of gaze following is when an individual looks where another person just looked. However, this should exclude instances when two individuals simultaneously look at the same object, such as after hearing a noise. A full understanding of gaze following incorporates a psychological concept of perception: An adult wants to *see* what the looker *perceives*. The developmental question is when does this understanding begin.

Before their first birthdays, infants track the looking behavior of people. However, in most situations, a person turns her *head* and her eyes toward a target object. Because of the multiple cues from the person, it is unclear which one infants follow. Infants could follow salient head movement, which could pull their attention in a direction and to the target by accident. By using motion salience, infants would not be gaze following at all. They would be responding to the person without understanding the importance of the person's eyes or perception.

To find evidence of gaze following, Brooks and Meltzoff (2002) tested whether infants follow eye gaze or head motion with an open- versus closed-eyes test. As is typical in gaze-following procedures, an adult directly faced the infant and then turned toward one of two targets. In this study, there were two conditions: open versus closed eyes. In one group, the adult made eye contact with the infant, silently turned her head, and looked at the object with open eyes. In the other group, she acted in the same manner, except that she had her eyes closed as she turned her head. This action provides a control for head motion. The manipulation helps to address an issue fundamental to perception because we see with our eyes and not our head. An important step toward the psychological interpretation of seeing is to recognize that eyes are essential for looking. If infants recognize that eyes allow visual contact with an object, they should only look at the target when the adult looks at it (with open eyes). If infants follow head motion, they should look at the target in both conditions – without regard for the adult's eyes.

The test revealed that infants at 18, 14, and even 12 months of age noticed the perceptual status of the adult's eyes (Brooks and Meltzoff, 2002). Infants at all three ages differentiated the adult's turns with open eyes from the ones with closed eyes. They rarely looked at the target in the closed-eyes condition even though the adult's nose and head moved toward the target. By 12 months of age, infants selectively looked at the

Figure 1 An example of gaze following: The adult silently turns to the target and then the 12-month-old infant follows her look. Reprinted from Meltzoff, A.N., Brooks, R., 2007. Intersubjectivity before language: three windows on preverbal sharing. In: Bråten, S. (Ed.), On Being Moved: From Mirror Neurons to Empathy. John Benjamins, Philadelphia, PA, p. 156, Reprinted with permission.

adult's target when her eyes were open: Infants were following eye gaze (**Figure 1**).

Infants also coordinated their own gaze with other social behaviors. They vocalized and pointed at the target. This combination is particularly striking given that children with ASD often have deficits with each of these behaviors (Kasari et al., 2008). The typically developing infants used these acts more often in the open-eyes than the closed-eyes condition. In addition, though the objects in the room remained the same, they acquired a special valence when the adult looked at them. Infants looked at the target longer when the adult could see it than when she could not. By 12 months of age, infants treated the adult's gaze like a psychological spotlight on the distal object.

When does gaze following emerge? To examine this issue Brooks and Meltzoff (2005) tested infants at 9, 10, and 11 months of age with the open- versus closed-eyes test. The results were intriguing because there was a developmental shift. At 9 months, infants did not discriminate open eyes from closed eyes. The 9-month-olds followed the adult's turns when her eyes were closed just as often as when her eyes were open. In contrast, at 10 and 11 months of age, there was a significant effect of eye status. For the closed-eyes group, 10- and 11-month-old infants refrained from following the adult's turns. In the open eyes group, they looked at the adult's target. These findings show that gaze following emerges by 10 months of age. By 10 months, but not 9 months of age, infants were truly following the gaze of the adult.

The evidence helps explain the behavior of 9-month-old infants and younger ages. Though infants as young as 3–4 months of age react to adults' looking behavior (Moore, 2008), they are not specifically following eye gaze. They are responding to the person regardless of whether her eyes are open or closed (Brooks and Meltzoff, 2005). The pattern suggests that young infants look in the direction indicated by head motion or postural changes. The findings support the conclusion that young infants are 'body following' and construe people as orienting in a direction.

In contrast to the younger ages, by 10 months of age, infants selectively follow the looks (not just the head turns) of a person to distal targets (Brooks and Meltzoff, 2005). This is a significant developmental change in infants' understanding of eye gaze. Just 1 month earlier, at 9 months of age, infants do not make this distinction. By 10–12 months of age, infants treat others as visual perceivers. The converging evidence suggests that infants link the looker to the target object (Brooks and Meltzoff, 2002; Flavell, 2004). The infants make this connection specifically when the person has open eyes, but not closed eyes. This is a crucial step in recognizing people as intentional perceivers. By 10 months of age, infants have achieved at least a minimum definition of gaze following because they look where a person's eyes point.

Change in Focus

In recent years, many researchers have introduced findings based on eye tracking software. In most studies, the eye tracker works with a 2-D display of prerecorded images of a person's looking behavior. The systems provide time-accurate coding of latency and duration of gaze fixations. The presentation format provides new opportunities to test how different conditions affect infants' gaze behaviors. For example, Senju and Csibra (2008) used an innovative 2-D design to manipulate the cues for social communication (e.g., eye contact or infant-directed speech) in a gaze-following procedure. As more research uses 2-D paradigms, it is important to consider how well the 2-D findings will generalize to the 3-D world. There may be differences in infants' reactions to these experiences. Infants may more readily learn from a real person than a 2-D image of a person (e.g., as with language learning, Kuhl et al., 2003). Future research should explore whether the same factors identified in 2-D tests hold true for in-person interactions.

Current and Emerging Direction in Theory and Research

Language Development

Research demonstrates that infants' gaze behaviors relate to their language development. Two behaviors – gaze following and alternating gaze – are significant factors. The other reviewed gaze behaviors, visual scanning and gaze cueing, have rarely been tested as predictors of language acquisition. Gaze following provides a potent means to learn words, because infants who follow gaze can identify what object is being labeled. (This works well because parents often look at what they are naming.) The empirical evidence shows that gaze following reliably predicts receptive and productive language. For example, infants with high gaze-following scores at 10–11 months of age later have rapid productive vocabulary growth through 24 months of age (Brooks and Meltzoff, 2005,

2008). This gaze-language relationship remains significant even after accounting for infants' cognitive abilities (Mundy et al., 2007).

Alternating gaze also has a link to vocabulary development. As infants look from an object to the parent, they can monitor what their parent talks about. Their gaze alternation also invites parents to name an object of the infants' choice (e.g., often called 'follow-in labeling'), and thus, infants' gazing promotes increased word-learning opportunities. The observational research reveals significant effects for both infants' alternating gaze and parents' follow-in labeling (Carpenter et al., 1998). Of interest, one-year-olds' alternating gaze relates to their later vocabulary, even after accounting for maternal labeling. In experimental tests of infants' word learning, by 16 months of age, infants look up at the adult's face during object naming and are able to learn words under conditions of follow-in labeling. By 18 months of age, they learn labels for objects whether or not the adult uses follow-in labeling (Sage and Baldwin, 2010). The converging findings demonstrate that infants' own gaze behaviors play a role in word learning.

Autism Spectrum Disorders

Gaze behaviors are also of interest because they are often an area of deficiency for children with ASD. Children with ASD generally have less interest in sharing attention. They often have other social deficits that make it difficult for them to learn about others' intentions and mental states (Baron-Cohen, 1995; *see* Autism Spectrum Disorders).

A concern is whether children with ASD notice and follow the gaze of others. In a prospective longitudinal study, infants later diagnosed with ASD scanned faces at 2 months of age as much as a typical infant, but they looked less at faces by 6 months of age (Jones and Klin, 2013). This reduced attention to the eyes after 2 months of age could lead to less experience with the social information that eyes express. Even by 3- to 4-years of age, children with ASD are less likely to respond to or initiate joint attention than children with typical development (Toth et al., 2006). Nevertheless, gaze following and alternating gaze are strong predictors of language for children with ASD. Given that gaze behaviors emerge early in typical development (e.g., before expressive language), assessments of and interventions on gaze understanding can affect long-term outcomes of the development of children with ASD (Kasari et al., 2008). The work in this field highlights the interconnectedness of gaze behaviors, language, and the development of an understanding of mental states.

Robotics

Infants' gaze behaviors are also instrumental in the field of robotics. The modeling of gaze behaviors is part of this growing interdisciplinary field of research. Engineers use developmental data to build models and to train robots to follow people's looks (Sage and Baldwin, 2010). For developmental psychologists, on the other hand, gaze following provides a test of what cues inform infants about agency. For instance, work with socially interactive robots allows for a detailed investigation of when an object becomes a social entity (Meltzoff et al., 2010). The robot in this study was metallic and had black circles for eyes (i.e., the edges of camera lenses). To an infant, would this piece of metal ever become a social agent with a gaze to follow? To test this question, infants observed the robot and an adult under different social conditions. In the experimental group, infants watched as the robot and the adult socially engaged (e.g., playing imitation games). In control groups, the robot or the adult used the same actions, but the two did not have a social interchange (e.g., the robot moved but the adult simply watched). The results showed that infants were more likely to follow the 'gaze' of a robot after they saw the robot's social exchange with a person than when a social interaction was not achieved. Other work has shown that when robots contingently interact with young children, the robot is treated like an autonomous social agent. These examples and others demonstrate that infants' gaze behaviors can help evaluate social-cognitive development (Meltzoff et al., 2009).

Theory of Mind

Gaze-following paradigms also provide insights into the development of the understanding of mental states, often called 'theory of mind' (*see* Theory of Mind during Infancy and Early Childhood and Cultural Variation, Development of). For example, to adults, eye closure and other barriers equivalently block line of sight. However in infancy, eye closure is different from other obstructions (e.g., blindfolds or walls). As previously discussed, at 12 months of age, infants rarely follow the head turns of an adult who has closed eyes. In contrast, 12-month-olds make an interesting 'mistake' – they follow the head turns of an adult wearing a blindfold just as often as one wearing a headband (Brooks and Meltzoff, 2002). The findings suggest that infants understand eye closure in advance of other barriers. There is an experiential difference between the different visual obstructions. Infants have extensive firsthand knowledge of eye closure from opening and closing their own eyes. These daily experiences may help them understand how eye closure affects their own and others' visual perception. If true, infants' own experiences could powerfully change what infants understand about other people's visual perception.

Meltzoff and Brooks (2008) put the self-experience proposal to a test by using a blindfold to block infants' views. During a gamelike activity the infant looked at toys on a table. The experimenter periodically interposed the cloth blindfold between the infant and a toy. This repeatedly gave 12-month-old infants the direct experience of being unable to see when the opaque blindfold was lifted in front of their eyes during the training experience. In a control condition, the blindfold cloth had a window in the center, so the cloth did not block the infants' view. As an additional control, there was a baseline group in which infants had no training with the blindfold's visual properties. Thus, only the opaque blindfold group had the firsthand experience of having the blindfold block their view of the world. To assess infants' learning, all infants saw the experimenter wear the blindfold during a gaze-following test. This was the first time that the infants saw the experimenter put the blindfold on her eyes. The blindfolded experimenter turned toward distal targets. The blindfold outwardly looked the same on the experimenter. Would the infants interpret the adult looking as a function of their own experiences?

The self-experience had a significant effect on how the 12-month-old infants interpreted the adult's behavior (Meltzoff and Brooks, 2008). Infants in the control groups (i.e., window and baseline groups) still followed the blindfolded adult's turns. These infants acted like the naïve 12-month-olds in the previous study. In contrast, infants in the opaque blindfold group stopped following the 'gaze' of the blindfolded adult. Infants generalized their experiences with the opaque cloth to their social partner. After being unable to see when a blindfold was in front of their own eyes, they subsequently inferred that the adult could not see in a similar situation. Hence, they refrained from following the adult's turns. Their experiences had an immediate effect and completely changed how they treated the adult. The implication is that infants' firsthand experiences helped them infer what others could (or could not) see.

Given the laboratory findings that infants' own experiences influence their social cognition (Meltzoff and Brooks, 2008), this leads to the theoretical question of what naturally occurring (daily) experiences affect development. Cultures vary in how they structure their social interactions, which could modify the frequency and type of social cues available to infants (Akhtar and Gernsbacher, 2008 for a review; *see* Joint Attention during Infancy and Early Childhood Across Cultures). As patterns of social interaction differ by culture, will infants differ in which skills they learn? For example, the infant's experience of being carried facing away or toward their mother could affect how much they follow their mother's gaze versus posture. In another vein, when cultural practices emphasize learning through observing others (Rogoff et al., 2003), these practices potentially improve how readily infants monitor the gaze and the actions of other people. They may become adept at observing the gaze of others from afar (i.e., even when the person is not directly interacting with them). Thus, the study of cultural practices would further illuminate the effects of children's own experiences on their understanding of others.

Conclusions

Examining infants' gaze behaviors helps illuminate social-cognitive development. The reviewed work demonstrates that infants gradually change their gaze behaviors. The proposed interpretation is that infants alter their behavior because they are developing a psychological interpretation of gaze. As infants decode the looks of other people, they can learn about what others see as well as what they talk about. Missing these essential gaze cues is especially noteworthy for children with ASD. Deficits in gaze behaviors may contribute to subsequent difficulties in language and social interactions for children with ASD. The gaze behaviors of infants with typical and atypical development are potentially interconnected to other social behaviors, such as pointing, social referencing, and prosocial understanding. The field of robotics offers opportunities to examine how acts become construed as socially meaningful by infants with typical and atypical development. Future work should further explore the interrelationships between the understanding of gaze and other aspects of social cognition, including face perception, goal detection (e.g., intentionality), and theory of mind.

Infectious Diseases: Psychosocial Aspects

Andrew Steptoe and Lydia Poole, University College London, London, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Infectious diseases, also known as communicable diseases, are illnesses caused by invasive pathogens such as viruses and bacteria. Psychosocial factors (including life stress, mood, social support, and coping responses) have been shown to influence the acquisition of infections such as the common cold, and the activation of latent infections such as genital herpes. Coping styles have also been shown to affect the course of infectious illness and the duration of symptoms. Several mechanisms are involved in mediating these effects, including the suppression of the individual's immune defenses, changes in the reporting of symptoms, and health-related behaviors such as smoking and physical activity.

Infectious diseases are caused by invasive pathogens, such as viruses, bacteria, fungi, and parasitic infestations. When the germ theory of disease was established by Pasteur and Koch in the nineteenth century, a mechanistic view of infectious disease became dominant, with illness depending on exposure to the agent and the virulence of the infection. However, the ascent of immunology in the mid-twentieth century shifted the balance toward recognition that the strength of bodily defenses plays a role in susceptibility to infectious disease.

Psychosocial factors are relevant to the experience of infectious disease in two principal ways:

1. Psychosocial factors may influence the acquisition of infection or the reactivation of latent infection. Much recent research on upper respiratory illnesses such as the common cold and on herpes virus infections (genital and oral herpes) has been directed at this possibility.
2. Psychosocial factors may affect the course of infectious illness once it is developed, influencing the duration and severity of symptoms.

Readers interested in more detailed overviews of psychosocial aspects of infectious disease are referred to more comprehensive reviews (Pedersen et al., 2010; Segerstrom, 2012).

Mediating Processes

There are four general processes through which psychosocial factors such as acute and chronic life stress, social support, and coping may influence the acquisitional course of infectious disease.

Exposure to Pathogens

Since infectious diseases are caused by pathogens, any changes in exposure that are stimulated by psychosocial factors may influence the chances of becoming ill. For example, some people respond to distressing events in their lives by seeking social support and mobilizing social networks. This might have the unwanted effect of exposing the individual to more respiratory infections. Alternatively, people may respond by social withdrawal, reducing contact with airborne pathogens. Differences in exposure to infections resulting from crowding and other factors probably account for much of the socioeconomic gradient observed in conditions such as infectious mononucleosis (glandular fever). Exposure to pathogens is a key issue in the prevention of outbreaks of serious waterborne, airborne, and sexually transmitted infections in the developing world, but little psychosocial research have yet touched on this topic. One study, which has addressed this issue, used data from the National Health and Nutrition Examination Survey III to examine the association between sociodemographic factors and pathogen burden in a sample of over 19 000 adults (Zajacova et al., 2009). The pathogens studied included *Helicobacter pylori*, cytomegalovirus, herpes simplex virus-1, and hepatitis B. These authors found that individuals with less education, lower income, and ethnic minority status were more likely to have been infected by these pathogens, probably because of greater exposure earlier in life than their more privileged counterparts.

Changes in Behavior

Health behaviors and lifestyle have an influence on infectious disease. Smoking, alcohol consumption, and physical activity all influence vulnerability to infection and the duration of symptoms. Malnutrition is probably the principal cause of diminished immunity and susceptibility to infection across the world. Although severe protein energy malnutrition is rare in developed countries, undernutrition is common among the elderly and impairs immune resistance. Other health behavior parameters such as sleep duration and physical exercise appear to influence the effectiveness of vaccination against infections (Edwards et al., 2008; Prather et al., 2012). If the pattern of health behaviors is altered in relation to psychosocial factors such as life stress, then the acquisition and course of infectious disease may be modified. Behaviors can have direct effects on infectious disease, such as when sexual behavior stimulates the reactivation of latent herpes virus, or the acquisition of human papillomavirus and risk of cervical cancer. Behaviors related to health service utilization are associated with socioeconomic status in the developing world, and play an important role in determining risk of diseases such as malaria (Onwujekwe, 2005). Moreover, behaviors surrounding health decision-making processes

such as uptake of the human papillomavirus vaccination have been found to be dependent on psychosocial factors such as cultural and religious beliefs (Marlow et al., 2009). Research investigating the influence of ethnic differences in such health programs is important, since greater insights will help tackle health inequalities.

Symptom Reporting

People vary substantially in the extent to which they attend to physical sensations and recognize them as symptoms of illness. Research on illness behavior has shown that the same infection may elicit quite different levels of complaint, work absence, and health service utilization, depending on levels of psychosocial stress. Negative affect also influences symptom reporting and illness behavior, with more symptoms being reported in distressed individuals independently of objective markers of illness (Howren and Suls, 2011).

Suppression of Bodily Defenses

The fourth possibility is that psychosocial factors influence susceptibility and the course of infectious disease by modifying physiological defenses. Depending on the infectious agent, skin abrasions, immune processes, or mucosal barriers may be involved. One of the principal interests in psychoneuroimmunology research has been the possibility that psychosocial factors reduce immune defense, allowing infections to become established that would otherwise be resisted. These hypothetical associations are illustrated schematically in Figure 1. The healthy response to infections involves the individual mounting an adequate defense that excludes the infection and prevents illness (upper panel). In contrast, the impaired response arises when exposure to the infectious agent takes place against a backdrop of compromised immune function due to adverse psychosocial stimulation (lower panel). Under these circumstances, illness may develop. This framework highlights the stress response as a key determinant of the acquisition and progression of infectious diseases via modulation of the immune system (Padgett and Glaser, 2003; Segerstrom and Miller, 2004).

These mediating processes are not mutually exclusive, and one of the difficulties in research on infectious disease lies in teasing out the various pathways through which the acquisition or duration of infection are affected.

Methodological Aspects

The processes mediating between psychosocial factors in infectious disease outlined in Section Mediating Processes have important implications for how research on this topic is carried out.

Verification of Infection

Interpretation of associations is enhanced greatly by objective verification of infection. If infection is assessed merely by the subject or a family member, then it is not possible to rule out symptom reporting biases, and spurious associations between psychosocial factors and unfounded symptoms may be identified. Objective verification allows the timing of infection in

Figure 1 Schematic outline of the links between infection, immune defenses, psychosocial factors, and illness.

relation to psychosocial stimuli to be established, so that causal sequences can be described. The most precise verification is possible in experimental studies of infection, where volunteers are infected deliberately with metered doses of virus or bacteria. The acquisition of infection then is assessed by culturing samples obtained some days later. Unfortunately, biochemical verification of infection is difficult and invasive in naturalistic studies, requiring repeated sampling of blood or nasal washes (for upper respiratory infection) from the individual under investigation. As an alternative, clinical examination by health professionals or trained observers is valuable for objectively assessing the occurrence of infection.

Standardized Measures of Symptoms

Since symptom reporting can be influenced by psychosocial factors independently of objective infection, it is important to reduce variability by employing standardized measures. These measures detail the number, type, and duration of symptoms. Work on upper respiratory infection, for example, typically assesses 10–14 standard symptoms of colds. Such indices are particularly useful in assessing the duration and severity of symptomatic episodes.

Measures of Health Behavior and Biological Factors

One of the most important implications of the discussion of mediators in Section Mediating Processes is that adequate measures are taken of social activity, smoking, alcohol consumption, sleep patterns, diet, and other health behaviors. Analysis of these variables will establish whether changes in health behaviors account for variations in vulnerability to infections. These measures often rely on self-report and so are subject to reporting and recall bias. Technological innovations have improved objective assessment of some behaviors such as physical activity and sleep (using accelerometers). Measurement of hormonal and immunological factors via blood and saliva samples is, of course, extremely interesting in developing an understanding of mediating biological processes (Steptoe and Poole, 2010).

Longitudinal Designs

Many studies of infectious disease have utilized cross-sectional or retrospective designs, with assessments of the frequency of infection in the past, along with measures of stress and other factors. Such studies have been used to find out whether the number of infections over the past month or year was greater among individuals who experience more life stress or have poorer social support than others. More recent work has focused on a life course approach to the study of infectious illness, trying to disentangle the role of early life exposure to psychosocial adversity on later disease vulnerability (Pace et al., 2006; Taylor, 2010). Cross-sectional and retrospective studies are limited in the inferences that can be drawn, since selective recall biases may operate. For example, it is possible that individuals with depressed mood will recall more episodes of infection, and also report more negative life experiences or poorer social support than others. As with many topics in health psychology, the most convincing data derive from longitudinal studies in which psychosocial factors are assessed prior to illness, so that prospective links can be established. Studies involving repeated measures of psychosocial, behavioral, and biological factors are particularly strong, since they allow the time course of vulnerability to be established.

Experimental Studies

Many studies have investigated factors such as stress in relation to infection in animal models. Animal studies do not suffer from many of the methodological problems inherent in human research, but are limited in terms of the subtlety of psychosocial investigation (Moynihan and Ader, 1996).

Experimental studies of infection in humans are of course rare, and are only justified for mild forms of disease. But an important program of work on colds and other upper respiratory tract infections has been conducted by Sheldon Cohen and colleagues in the USA and UK that throws considerable light on the role of psychosocial factors. In these studies, volunteers free of infection are inoculated with standard doses of the virus responsible for the common cold or influenza. If an appropriate dose is administered, not everyone will become ill. Differences in the subsequent rates of infection and illness must, therefore, be due to differences in vulnerability. Social activities are limited by quarantine, and health behaviors such as smoking are controlled, so psychosocial impairment of bodily defenses can be evaluated.

Cohen et al. (1991) demonstrated with this paradigm that susceptibility to common cold viruses was associated directly with a psychological stress index created through an amalgam of measures of major life events over the past 12 months, perceived stress and negative affect. The dose–response association was independent of age, allergic status, and other risk factors. Later work has established that chronic stressors such as long-term work problems and relationship difficulties are particularly relevant. By contrast, social networks have a protective effect, with lower susceptibility to experimental infection among volunteers with more extensive and diverse social networks. Cohen et al. (1997) found that the rates of infection and illness were more than four times greater in volunteers with limited social networks, compared with high social networks, after adjustment of control variables. It has also been demonstrated that susceptibility to infectious illness is reduced in people from low socioeconomic status background in childhood independently of adult social status (Cohen et al., 2004), and in people who report poor sleep (Cohen et al., 2009), while positive affect is protective (Cohen et al., 2006).

These studies have established clearly that psychosocial factors can influence vulnerability to infectious disease and can account in part for interindividual variability in susceptibility. They have also begun to identify psychobiological mediators, with evidence that associations between psychological stress and the severity of symptoms are related to the levels of the inflammatory cytokine interleukin-6 production in the nasal passages following influenza administration. This suggests that inflammatory mediators may be involved in symptom production in stressed individuals. Cellular aging is also

implicated, with an association being described between short leukocyte telomere length and venerability to experimentally administered rhinovirus (Cohen et al., 2013).

Colds and Upper Respiratory Illness

Upper respiratory illnesses are caused by many different types of microorganism. The common cold is a viral infection, and more than 200 different viruses have been implicated. Acute sore throats are commonly caused by streptococcal bacterial infection, while influenza is a viral disease. Naturalistic studies of psychosocial factors in upper respiratory illness involve assessing spontaneous illnesses in people living their everyday lives. They have shown similar effects to those identified in experimental studies, albeit with less control over confounding factors (Pedersen et al., 2010). For example, some studies have followed volunteer populations over several months with periodic measures of life stress, coping, health behavior, and illness. It has been demonstrated in both adults and children that susceptibility to colds is greater in people who experience high rather than low life stress. Interactions between life-events stress and social support have also been observed, with lower incidence of colds among individuals reporting high support. In addition, episodes of upper respiratory infection have been shown to be preceded for 1 or 2 weeks by high levels of perceived stress or a high frequency of minor life events (hassles). Since the acquisition of an infection is followed by several days of incubation, studies of this kind suggest that the pathways outlined in **Figure 1** (lower panel) may be operating. However, obtaining detailed neuroendocrine or immunological data in naturalistic studies remains a methodological challenge to researchers, and it is possible that some of the associations observed are due to changes in exposure to pathogens rather than psychobiological influences on bodily resistance.

Psychosocial Influences on Symptoms

The interaction between the brain and the immune system is two way, with behavioral function being affected by immune responses as well as psychosocial factors influencing the immune system. It is now recognized that the behavioral concomitants of infectious disease such as lethargy, loss of appetite, increased sleep, and loss of interest in the outside world, collectively termed 'sickness behavior,' are stimulated in part by immune products such as interleukin-1 (Dantzer et al., 2008). These cytokines are released as part of the biological response to infection, and help to coordinate the pattern of behavior that conserves and protects the organism, and may thereby be adaptive in promoting survival.

In humans, psychosocial factors not only affect susceptibility, but also the duration and severity of symptoms. For instance, one study assessed the duration of symptoms of naturally occurring colds in a sample of children (Turner Cobb and Steptoe, 1998). Prior to the study, patterns of coping had been assessed with standardized measures. It was found that children who typically dealt with stress using problem-focused coping strategies tended to suffer from colds for a relatively short time. In contrast, children who stated that they used avoidant coping strategies such as distraction and social withdrawal experienced colds of longer duration. These effects remained significant after statistical adjustment for gender, age, family composition, social class, parental smoking, and parental alcohol consumption. It is possible that those who used distraction and avoidant coping strategies failed to respond directly to their illnesses, and did not take the necessary steps in terms of self-care and activity restriction that might prevent lengthy episodes of symptomatic disease (Falagas et al., 2010).

Recurrence of Herpes Virus Infections

Herpes simplex viruses cause a range of diseases, the most common of which are oral herpes (cold sores) and genital herpes. Different types of herpes virus cause the two diseases. Both forms of herpes infection are common and typically benign, though they may cause considerable distress. In more than half of cases, the virus is not eliminated following first infection, but becomes permanently established in sensory ganglia. In some individuals the virus is reactivated periodically, and this leads to a recurrence of infection. Reactivation is partly under immunological control, and may take place when immune surveillance is impaired by psychosocial factors.

Studies of both types of herpes infection have been carried out which suggest that, in some cases, recurrence of infection is preceded by periods of negative mood or stress. Colds also seem to be important in the triggering of recurrent oral herpes. A meta-analysis of 11 prospective studies indicated that psychosocial stress was associated with recurrence of herpes simplex virus infection (Chida and Mao, 2009). However, the models of stress that have been employed in this area have been very varied, including exposure to negative life events, mood, and daily hassles. Greater work is needed to evaluate the interaction between stressors and psychosocial coping resources.

Another type of herpes virus is Epstein–Barr virus (EBV), responsible for infectious mononucleosis (which may present as a sore throat). A few studies have shown that stress and negative moods are associated with this type of infection. Interestingly, there is also psychoneuroimmunological work that throws light on the role of EBV. It has been shown that antibody titers for EBV are raised by life stress, for example, during the period prior to important academic examinations, or in people experiencing marital conflict (Kiecolt-Glaser et al., 1988). A raised antibody titer suggests that EBV has been reactivated and allowed to replicate due to failure of immune control. If unchecked, the reactivation may lead to fresh episodes of illness.

Other Infections

One important type of infection with extensive psychosocial ramifications is human immunodeficiency virus; this will not be discussed here, since it is examined elsewhere in the Encyclopedia. Other types of infectious illness such as urticaria, streptococcal throat infection, and tuberculosis have also been studied, but data are too limited to draw general conclusions. A large range of more severe infections such as poliomyelitis, rabies, and salmonella have been investigated in animals, with

evidence for increased vulnerability with exposure to psychological stressors (Rabin, 1999). However, there are important variations with species, age, concomitant disease and prior exposure, and these make it difficult to draw simple inferences for humans.

Conclusions and Future Directions

It is likely that research on psychosocial influences on infectious disease will become increasingly important over the next decade. One reason is that it is now recognized that infection and inflammatory processes play an important role in 'noninfectious' diseases such as coronary heart disease. Smeeth et al. (2004) observed that risk of acute myocardial infarction or stroke was elevated in the first 3 days following the diagnosis of a systemic respiratory tract infection, and it is possible that influenza vaccination is protective (Warren-Gash et al., 2009). However, limited psychosocial research on this and other conditions from the perspective of infection has been carried out. Indeed, most research on psychosocial aspects of infection has been conducted on a limited group of infections, and much remains to be learned about resistance to fungi, parasites, and other microorganisms. The recognition of the importance of psychosocial factors in vulnerability and adaptation to infectious disease may lead to new and more effective methods of helping people cope with these illnesses.

Abstract

An inference is defined as the information that is not expressed explicitly by the text but is derived on the basis of the understander's knowledge and is encoded in the mental representation of the text. Inferencing is considered as a central component in discourse understanding. Experimental methods to detect inferences, established findings, and some developments are reviewed. Attention is paid to the relation between inference processes and the brain.

When listeners or readers understand discourse, they understand much more than what is stated explicitly in the sentences. On the basis of their knowledge of the language and the world, they are able to understand what has been left implicit in the text but is intended to be communicated.

Consider the following text (a):

(a) There were municipal elections yesterday. Because the majority of the lower town voted for the local party, there was a shift toward the left in the city council. But the right-wing party was not completely disappointed. It had expected to lose much more.

In text (a), readers can infer that the local party is a left-wing party; that there is a causal relation between many people voting for a particular party and that party getting a stronger representation; that there are height differences in the town and that the town is probably located on a river bank; that the city council used to be more right oriented; that there is a contrast between the shift toward the left and not being completely disappointed, and consequently that the shift is a reason for being disappointed and that there are other reasons (worse expectations) why the right-wing party was not so disappointed; and that 'it' refers to the right-wing party and not, for example, to the city council. All these pieces of information are not stated explicitly in the text, but readers do understand them. They are called inferences.

An inference is defined as information that is not expressed explicitly by the text but that can be derived from the text on the basis of the comprehender's knowledge and that is encoded into the representation the comprehender constructs of the text. In this article, the notion of inference is restricted to the derivation of implicit information that occurs in spontaneous language processing. These inferences are distinguished from logical deductions in reasoning and problem solving (Johnson-Laird, 1983; see also *Reasoning with Mental Models*), such as the logical deduction 'Some artists are chemists' from the premises 'Some beekeepers are artists. All beekeepers are chemists.' Logic is concerned with the assessment of the validity of arguments in reasoning. Although listeners and readers certainly make logical deductions, and some inferences can be considered as logical inferences, everyday language behavior is not characterized by the evaluation of the validity of the arguments in reasoning.

Two kinds of inferences might be distinguished. The first kind is an inference that is the derivation of new information. This is what in ordinary language is called an inference. For example, from the sentence 'John selected his stranston shoes because there was much mud,' the reader can infer that apparently stranston is a material or brand that has advantages if there is much mud. Given that the reader is not familiar with stranston, the reader cannot know that the conjunction 'because' is correctly used. However, by assuming that the sentence makes sense, the reader can derive the inference as new information. The second kind of inference is an activation of available knowledge. Examples from text (a) are that 'it' refers to the right-wing party, and that, given the contrastive relation indicated by 'but,' a shift toward an opponent party is in general a reason for disappointment. This kind of inference in general is not called an inference in everyday language, but most of the psycholinguistic research focuses on this kind of inference.

Issues in Inference Research

There are several issues that make inferences an important topic of research in language understanding. In understanding a discourse, the number and variety of inferences that may be derived from the discourse seem to be almost unlimited. This may lead to a computational explosion. Yet, the human processing system has limited capacity, and comprehension is accomplished too quickly for many time-consuming inferences to be made. Therefore, the first issue is how to account for the control of inferences: Which inferences are made and which ones are not made? This issue will be discussed in Section Some Established Findings in Inference Research. The second issue concerns the inference as a process. What constitutes the process of making an inference; how does the inferred information get activated and deactivated; how does the information in the text interact with the reader's knowledge? Some aspects of the process of inferring will be discussed in Section Toward a More Differentiated View on Inferences. Two additional issues will be discussed that reflect the development in inference research in the last decade. First, until recently, inferences were considered as a rather isolated phenomenon, while in current research inferences are considered as one of the

components of the comprehension process (Section Inferencing as One Component of Discourse Comprehension). Second, the advent of methods to measure brain activity leads to a better understanding of the relation between inferences and the brain (Section Inferences and the Brain). This overview focuses on inferences in reading, but most of the results apply to listening as well.

Methods in Inference Research

Whether an inference is made and when it is made can be investigated by measuring specific aspects of the reading behavior. The measurements are made during the reading of the words or sentences that trigger the inference (*online methods*) or after reading those words or sentences (*off-line methods*).

Off-line Methods

The assumption underlying off-line methods is that the inferences are encoded into the mental text representation, similar to information that is expressed explicitly by the text. Therefore, they can be investigated in tasks such as reproduction, recognition, and verification. In a reproduction task, the reader is required to reproduce the text after having read it. Information that was not stated explicitly in the text but that is reproduced by the reader is supposed to be inferred by the reader. In a recognition task, the reader has to judge whether particular words or sentences occurred in the text. The rationale of the recognition task is similar to that of the reproduction task. Information that is incorrectly judged as having appeared in the text is assumed to be inferred. Many people who had studied the sentences 'John was trying to fix the birdhouse. He was pounding the nail when his father came out to watch him and to help him do the work' incorrectly recognized the sentence 'John was using the hammer to fix the birdhouse when his father came out to watch him and to help him do the work.' This indicates that an instrumental inference (hammer) was made (Bransford and Johnson, 1973). Reproduction and recognition tasks can indicate whether the inferences are made but in general cannot distinguish whether the inferences are made during reading (at encoding) or during the measurement (at retrieval). In a verification task, readers judge whether the content of a sentence is true or false with respect to the content of the text. Not only the accuracy, but also the reaction time for the verification or the recognition is important. If inferred information is recognized or verified as quickly as explicit information, this is an indication that the inference is made during reading, and not at the moment of the off-line task. Off-line methods are used frequently in combination with online methods to answer the question of when inferences are made.

Online Methods

Online methods are employed during reading and aim to detect the ongoing inference process immediately. The assumption is that inference processes require time. Therefore, they are detected by a long reading time at the moment the inference is made, relative to a control condition in which no inference is made. Reading times are measured in a self-paced reading task in which the reader by pressing a button exposes successive units of text (words or clauses) in a window on a computer screen. The interval between button presses is defined as the reading time for the unit of text. For example, for understanding the second sentence in 'Mary got the picnic supplies out of the car. The beer was warm,' the inference is required that there was beer among the picnic supplies. Therefore, the reading time for the second sentence in this sequence should be longer than in the sequence 'Mary got the beer out of the car. The beer was warm' (Haviland and Clark, 1974). Reading times are also measured in eye-tracking recordings that reveal what the reader looks at and how long. This makes it possible to measure fairly exactly when the inferences are made. Just and Carpenter (1978) found that the gaze duration on 'killer' in 'The killer left no clues for the police to trace' is longer if this sentence is preceded by the sentence 'The millionaire died on a dark and stormy night' than if it is preceded by the sentence 'The millionaire was murdered on a dark and stormy night.' Reading the word 'killer' requires the information that the person was murdered; this information has to be inferred after 'die' and is explicit in 'murdered.'

Another online method is measuring event-related potentials (ERPs), changes in the electric encephalogram due to activities in the brain. This technique is very time sensitive and therefore can reveal ongoing reading processes. Van Berkum et al. (2005) showed that hearers of a discourse make predictions of an upcoming noun. The noun was preceded by a gender-marked adjective whose suffix matched or mismatched the predicted noun. For prediction-inconsistent adjectives, a positive inflection in the ERP wave was observed 50–250 ms after onset of the inflection (before the noun), indicating that listeners anticipate an upcoming word. In addition, a negative inflection was observed at about 400 ms from noun onset, which is generally observed when a word does not fit very well in the context.

Other methods are administered immediately after the reading of the word or sentence that triggers the inference and can also be considered as online methods. In these tasks, a word is presented as a probe during reading, at or shortly after the moment that the inference is supposedly made. The probe is related to the information that is presumably inferred. An example is the probe word 'break' after the sentence 'No longer able to control his anger, he threw the delicate porcelain vase against the wall.' The task may be to decide whether or not the string of letters of the probe forms a word (*lexical decision*), to decide whether or not the probe word had been presented in the previous sentence(s) (*probe recognition*), or to pronounce the probe word (*naming*). The assumption is that if the inference is encoded into the text representation, the lexical decision time for the probe and its naming time are shorter and the time needed to indicate that 'break' did not occur in the text is longer than in a control condition (see Section The Process Character of an Inference) in which the inference is not made. The status of the different lexical techniques is not quite undisputed. In some investigations, it is claimed that these lexical tasks are sensitive to transient activations (i.e., inferences that are activated only for a short time) rather than to inferences. In particular, naming is sometimes considered a task that does not

reflect the nature of the text representation and, accordingly, does not reflect inferences that are encoded in the text representation. In other studies, it is suggested that lexical decision and probe recognition, in contrast to naming, register the fit of the probe with the preceding context rather than the encoding of inferences.

Some Established Findings in Inference Research

The issue that has stimulated much psycholinguistic research on inferences since the early 1970s is the following question: Which inferences are made and which ones are not made? This issue was investigated by looking for classifications of inferences, on the assumption that some kinds of inferences are made during reading and some other kinds are not.

A common distinction is between *necessary* and *elaborative inferences*. Inferences are called necessary if without them the text representation is not coherent. Inferences that are not necessary for coherence are called elaborative, optional, or embellishing. Two aspects of coherence can be distinguished. *Referential coherence* is achieved by the fact that a sentence in a text deals with entities that are expressed earlier in the text. Linguistic devices to indicate referential coherence are referential (or anaphoric) expressions, such as pronouns and definite noun phrases that refer to an antecedent in the text (*see Anaphora Resolution*). *Relational coherence* is achieved by the fact that the content of a sentence has a conceptual relation with other sentences, such as a causal, contrastive, or concessive relation. Relational coherence can be expressed by conjunctions. If, in text (a) above, the inference about the coreferentiality between 'it' and 'party' or the inference about causality between 'voting' and 'shift' is not made, there is no coherence between the sentences. The pronoun 'it' is considered as an instruction to find a particular referent; the conjunction 'because' is considered as an instruction to find a causal relation in the context. If such instructions are not executed, the representation is not coherent. In this way, inferences triggered by referential expressions and conjunctions contribute to the coherence of the representation.

The notion of *necessary inference* is sometimes defined in a different way and contrasted with *pragmatic inference*. An inference is necessary if it follows logically from the propositions in a text. From 'John is taller than Pete and Pete is taller than Bill,' it follows that John is taller than Bill. The causal inference between the propositions with 'voting' and 'shift' in text (a) is not only necessary for the coherence, but also necessarily follows from the text. It can be deduced from the conjunction 'because' and is called a conventional implicature.

Inferences that do not follow logically from the text are called pragmatic inferences. An example is the inference that the vase broke from the sentence 'John slipped on the wet floor and dropped the vase.'

Another distinction that is made frequently is that between *backward* and *forward inferences*. Backward inferences relate the current part of the text to an earlier part. Forward inferences anticipate information that might be expressed in the subsequent text. Backward inferences contribute in general to the coherence of the text and are in that sense necessary inferences, while forward inferences are not. Backward inferences are much more restricted than forward inferences; the reader can anticipate a great number of things.

Inferences can also be classified with respect to their content. This yields a list of inferences that can be extended *ad libitum*. It includes inferences about instruments, causes, consequences, goals, time, place, and protagonists.

Established findings in inference research (Singer, 1994, 2007; Van den Broek, 1994; Garrod and Sanford, 1994) are that necessary inferences – that is, inferences that achieve coherence between sentences – are made during reading. These inferences are in general backward inferences. Elaborative, embellishing inferences are in general not made during reading, except when they are highly constrained (O'Brien et al., 1988; Garrod et al., 1990); they are not required for comprehension. They are in general forward inferences. There are many possible forward inferences that can be made, and since they do not achieve coherence, there is no motivation for making them. Inferences that can necessarily be derived from the text are far from always made; in general, it depends on whether they contribute to the coherence or not.

Toward a More Differentiated View on Inferences

The research discussed in the previous section can be characterized by two views on inferences. First, inferences were considered as dichotomous entities: They are made or not made. Second, inferences were described with respect to their function in the text: Whether they are made or not depends on whether they contribute to the coherence of the text. Since the late 1980s and early 1990s, there has been a gradual change in inference research. These changes will be discussed in two subsections. First, the dichotomous view on inferences is being replaced by a process view on inferences: What happens if an inference is made? Second, attention has shifted from the function of inferences in the text to the availability of information and knowledge as determinants of inferences, and in this way to the role of the reader.

The Process Character of an Inference

The shift in attention toward a process view on inferences was stimulated by research on forward inferences. Presumably, the reason was that backward inferences were well established and that the idea that forward inferences are not made was not quite convincing. Several studies (McKoon and Ratcliff, 1986) demonstrated that forward inferences about very predictable events can be made, but are only partially or minimally encoded. After presentation of several sentences, among them, 'The director and the cameraman were ready to start shooting when suddenly the actress fell from the 14th floor,' the word 'dead' was presented as a probe for recognition. If an inference about dying were encoded in memory, it would interfere with the correct answer 'no.' When the target word was preceded by another word from the same sentence, an interfering effect did indeed occur, but when the target word was preceded by a neutral word (e.g., 'ready'), no interference occurred. This result was interpreted as evidence for a minimal encoding of the inference, such as 'something bad happened,' because a prime word from the same sentence

was necessary to strengthen the match between the probe word and the memory representation.

Other research demonstrated that inferences are built up and decay over time. First, forward inferences are not generated until some time after the presentation of the words the inference is based on. Experiments in which the time between the context that primes the inference and the presentation of a target word to detect the inference is varied indicate that a delay of about 1 s is necessary for the inference to be built up (Calvo et al., 1999). This observation may explain why no evidence for forward inferences was obtained in most of the earlier studies. If, in a reading experiment, subsequent information that does not support the inference is presented very quickly, the inference is not built up. However, if readers can read at their own pace or if subsequent information supports the inference, forward inferences can be built up. Second, an inference can be made for a brief period of time. It need not remain active. Keefe and McDaniel (1993) found that the naming latency for the word 'break' was shorter after 'One day, no longer able to control his anger, he threw a delicate porcelain vase against the wall' than after the control sentence 'One day, unable to control his impulses, he went out and purchased a delicate porcelain vase' when the probe word was presented with a short delay after the target sentence, but there was no facilitation when there was an intervening sentence between target sentence and probe. They argued that predictive inferences are drawn but are quickly deactivated. The likelihood that predictive inferences are encoded seems to increase if the information to be inferred is foregrounded and salient, and if the inference concerns a causal relation (Klin et al., 1999). In addition, the specificity of predictive inferences increases as the contextual support increases (Lassonde and O'Brien, 2009). With respect to the predictive inferences found by Van Berkum et al. (2005), one might hypothesize that since listening is slower than reading, more inferences are made during listening than during reading.

Availability of Information and Reader's Knowledge as Determinants of Inferences

Whether inferences are made or not depends not only on the function of the inference in the *text*, but also on whether the *reader* has information and knowledge available. This has been acknowledged in two well-known theories of inferences: the *minimalist theory* and the *constructionist theories*. In the minimalist theory, language processing and inferencing are described largely in terms of bottom-up processing of the information in the text. In the constructionist theories, the reader's search for meaning and the reader's knowledge play an important role, so that understanding entails a considerable amount of top-down processing.

In their minimalist theory on inferences, McKoon and Ratcliff (1992) argue that only two kinds of inference are drawn spontaneously during reading: inferences that serve to achieve *local coherence* and inferences that are based on *easily available information*. Local coherence refers to coherence between propositions that are not farther apart in the text than one or two sentences. Information is easily available if it is expressed in the current two or three sentences or if it is well-known general knowledge, such as instances of categories (collie – dog). In this way, the availability of information in the text is defined in terms of the linear structure of the text.

In constructionist theories, the knowledge of the reader plays a much more important role than in minimalist theory. According to constructionist theories, readers construct a *mental model* or a *situational model*. Such a model contains not only information in the propositions of the text but also information that is constructed by the reader, including elaborative inferences and global inferences (Johnson-Laird, 1983; Garnham and Oakhill, 1996; Zwaan and Radvansky, 1998). Many participants (Bransford and Johnson, 1973) who heard a sentence such as 'Three turtles rested on a floating log and a fish swam beneath them' recognized, incorrectly, the sentence 'Three turtles rested on a floating log and a fish swam beneath it,' but participants who had heard the sentence 'Three turtles rested beside a floating log and a fish swam beneath them' did not often recognize incorrectly the sentence with 'it.' Apparently, comprehension requires the activation of knowledge about spatial relations.

The central idea in the constructionist theory of Graesser et al. (1994) is that reading is considered as a search for meaning. The readers' goal and knowledge guide the reading process. Readers try to construct a meaning representation that is coherent both at the local and at the global level. They try to explain the actions, events, and states mentioned in the text; that is, readers try to answer 'why' questions with respect to the text. According to this theory, inferences concerning causal antecedents and superordinate goals are made because they explain actions in the text, whereas inferences about causal consequences and subordinate goals and states are not made because they do not contribute to the explanation. In evaluating minimalism and constructionism, one should keep in mind that even local inferences are not made if they do not address information that is part of the reader's knowledge (Noordman and Vonk, 1992).

Inferencing as One Component of Discourse Comprehension

In the studies reviewed up till now, inferences were considered as a rather isolated phenomenon. The main question was whether inferences are made or not, and the answer was considered to depend on the kind of inferences: bridging, forward, elaborating, instrumental, etc. In an earlier overview on inferences in discourse, Vonk and Noordman (2001) concluded that progress in inference research will be made only if inferences are no longer considered as a rather isolated phenomenon, but a component in discourse comprehension. Inferences should then be considered in relation to models of discourse comprehension and attention should be paid to the crucial role of world knowledge. This is indeed what happened to certain extent in the last decade. Once one considers inferences as a component in the comprehension process, it becomes clear that minimalism and constructionism are compatible. Discourse comprehension is, like all cognitive activities, *memory-based*: The processes take place in working memory and make

contact with information in long-term memory, which comprises information both from the previous discourse and from world knowledge. A crucial concept in the minimalist theory of inferences is 'easily available information.' But since easily available information includes previous discourse, world knowledge, knowledge about the topic of the text, about the goals of the protagonist (who can be referred to by a pronoun, testifying for its accessibility), and about the text structure, it does not follow from this notion that only a few inferences are made. For example, given that immediately available information includes world knowledge related to a specific word, it is not clear why minimalism would predict that the inference 'spoon' is not made when reading a sentence 'John stirred the coffee.' Interesting in this respect are data from *embodied cognition* showing that when reading sentences that describe a particular action similar activity is observed in the brain as when performing that action. Why would minimalism claim that the instrumental inference for 'stirring coffee' is not made, while inferences about the waiter, the menu, and the bill are made in a restaurant script story? Whether the inferences are made or not is, of course, an empirical question, but the prediction does not follow from the minimalist position. Other examples are studies by Albrecht and O'Brien (1993) and Myers et al. (1994). Given that the protagonist and his or her attributes are active during the whole story, it is not surprising – and it does not refute minimalism – that there is an increase in reading time for 'she ate a cheeseburger' if the protagonist was introduced earlier in the discourse as a vegetarian. To further strengthen the conciliation between minimalism and constructionism: it is not clear why some findings are considered to support constructionism and to argue against minimalism. Consider the beginning of a story 'Valerie left early for the birthday party' vs 'Valerie left the birthday party early' followed by a number of sentences including 'She spent an hour shopping at the mall' (Graesser et al., 1994). World knowledge about 'left for' and 'left' makes clear that the birthday party is an upcoming episode or a terminated episode, respectively. Consistent with the view that readers keep track of the temporal development in a story (Bestgen and Vonk, 1995; Zwaan and Radvansky, 1998), the birthday script is relevant and available only in the 'left for' version, which was evidenced by a test sentence. This explanation of the results is not in conflict with minimalism at all. It shows that the constructionist theory is not incompatible with memory-based processing. And this claim can be made stronger. In the constructionist view, reading is considered as a search after meaning and explanations. The goal dictates what kind of knowledge the reader is after and activates specific knowledge and makes it available. It determines what information is in focus. The reader's goal can affect the processes in working memory and interact with long-term memory. The search after meaning of this explanation-based approach can be accommodated in the memory-based approach. The position of Gerrig and O'Brien (2005) is in agreement with our proposal. "There is no need to define categories of inferences that readers will typically encode and those that readers are less likely to encode. Inferences are encoded to the extent that information in active memory makes contact with relevant or necessary information from inactive portions of the discourse model and general world knowledge" (p. 236). They also suggest that the search-after-meaning of the explanation-based view can be accommodated in the memory-based view: "within the memory-based view, the concept of search-after-meaning is not actually a search of memory; instead it is an attentional, resources-consuming … process" (p. 237). What is less clear, however, is how this memory-based view on inferences can be invalidated, since all cognitive processes are memory processes.

Less progress has been made in relating inferences to models of discourse comprehension and to the crucial role of world knowledge. Most of the models of discourse incorporate world knowledge, but not in a computational way (Frank et al., 2008). In a memory-based model, world knowledge of the previous discourse and world knowledge are supposed to resonate. The Resonance model (Myers and O'Brien, 1998) is the example *par excellence* of memory-based processing. But the model does not incorporate world knowledge and does not claim to do so. The Construction–Integration model (Kintsch, 1988, 1998) has been a fruitful framework for the interpretation of experimental data and the generation of further research. The model accommodates inferences, but the implementation of world knowledge is rather ad hoc and restricted to text-relevant knowledge. This also is true for the Landscape model (Van den Broek et al., 1999) and the model by Langston and Trabasso (1999). On the other hand, the Distributed Situation Space model (Frank et al., 2003) encodes world knowledge based on events in a microworld. Therefore, world knowledge in this model is not introduced ad hoc and the model predicts inferences in the microworld in a computational way. The question, of course, is whether the model can be scaled up to more realistic amounts of knowledge. This problem applies to the other models as well.

Inferences and the Brain

The advent of techniques that measure brain activity is an important step in the study of discourse processing. One such technique is measuring ERPs. The ERP signal is a pattern of positive and negative peaks in the EEG. Hagoort et al. (2004) showed that when a word in a sentence violates world knowledge, this is reflected by the N400 in the brain wave. In the study by Van Berkum et al. (2005) cited earlier, differential ERP effects were found when an upcoming word matched vs mismatched a prediction.

Kuperberg et al. (2011) investigated inference processes in understanding sentences that have different degrees of causal relatedness. Lexicosemantic co-occurrence was held constant across the conditions. Critical words in the causally unrelated sentences evoked a larger N400 than critical words in both the highly related and intermediately related sentences. This was the case both when the critical words occurred before and at the end of the sentences. These data demonstrate that readers are immediately sensitive to coherence breaks. Causal coherence at the situation level immediately influences inferencing during semantic processing of incoming words. At many of the electrode sites, the amplitude of the N400 to critical words in intermediately related sentences fell in

between the amplitude of the N400 in the unrelated and highly related conditions. Interestingly, the linear relation between causal relatedness and the amplitude of the N400 differs from curvilinear relations obtained in a functional magnetic resonance imaging (fMRI) study by Mason and Just (2004) in brain activation and Myers et al. (1987) in recall. One possible interpretation, according to Kuperberg et al. (2011), might be the difference in temporal resolution between ERP and fMRI.

An interesting topic is the mapping of cognitive processes to regions in the brain. In general, it is assumed that processes in language understanding, such as word coding and syntactic analysis, activate the left hemisphere. There is increasing evidence, however, that the right hemisphere is also involved in language processes and in particular in inferencing. Beeman et al. (2000) showed in a visual hemifield study that predictive inferences activate the right hemisphere. Reading the sentence 'The space shuttle sat on the ground, waiting for the signal' might lead the reader to the predictive inference that the shuttle is taking off. This would lead to facilitation of the target word 'launch.' When this word was presented to the left visual hemifield (corresponding to the right hemisphere), the naming latency for this word was shorter than for an unrelated control word. But presenting the target word to the right visual hemifield, there was no difference between target and control word. According to the coarse semantic coding theory (Beeman et al., 1994), the right hemisphere is involved in the representation of wider connections of word meanings and less central meanings of words. This representation includes distant associations between words. Since these associations play a role in the processing of inconsistencies and in inferencing, in particular when there is no direct overlap between adjacent pieces of text, it is supposed that the right hemisphere is involved in inferences. Interestingly, for causal inferences that require bridging inferences, Beeman et al. (2000) found that the left hemisphere is responsible for the inferences after the shuttle sat on the ground. When the shuttle disappeared into space,' the word 'launch' is processed faster than a control word when it is presented to the right visual hemifield, but not when it is presented to the left visual hemifield.

Virtue et al. (2006b) investigated in a visual hemifield study bridging and predictive inferences that were either strongly or weakly constrained by the context. A target word related to the inference was presented in one of the visual fields for lexical decision. For strongly constrained bridging and predictive inferences, facilitation (shorter lexical decision time for target words in the inference condition than in a control condition) was obtained in both hemispheres. For weakly constrained bridging and predictive inferences, there was greater facilitation in the right hemisphere than in the left hemisphere, but for predictive inferences there was some facilitation in the left hemisphere as well.

Mason and Just (2004) used fMRI to study the neuroanatomical basis for inference processes in reading. This is a technique that measures activity in specific brain areas by detecting changes in blood flow. It is less sensitive to temporal resolution than ERPs. Mason and Just (2004) used sentence pairs of Keenan et al. (1984) and Myers et al. (1987) but only in three versions: the distantly related, moderately related, and highly related versions. In the right hemisphere, there was greater activity for the moderately related sentence pairs than for the highly related and the distantly related pairs. In the left hemisphere, there was no difference between the three versions and the activation for the highly related and distantly related versions was greater than in the right hemisphere. These results were interpreted to mean that the left hemisphere is concerned with processing the sentences, while the right hemisphere is responsible for establishing the coherence and presumably for making the inferences.

Kuperberg et al. (2006) used in an fMRI study similar items as Mason and Just, but they had items of three sentences long instead of two. In addition, they changed the experiment in some methodological ways (e.g., increasing the number of items and testing only on the last sentence instead of on two sentences). In the intermediately related condition, processing required more time (participants had to judge the coherence of the sentences). For the intermediately related sentences (compared to the other two conditions) they found increased activity in both hemispheres (left lateral temporal/inferior parietal/prefrontal cortices, the right inferior prefrontal gyrus, and bilateral superior medial prefrontal cortices). Apparently, understanding information that is not explicitly stated in the discourse is accompanied by the activation of a large cortical network in both hemispheres.

Interesting as it is to identify the areas that are activated, more interesting is what localization data can contribute to a theory of inferencing. A distinction is frequently made between the generation of inferences and the integration of the inferred information in long-term memory (Mason and Just, 2004). Is there experimental evidence from brain studies for this distinction? Mason and Just suggest that these processes correspond to two large-scale cortical networks: a reasoning system in dorsolateral prefrontal cortex for generating inferences and specific parts of the right-hemisphere for integrating the possible inferences that have been generated. Kuperberg et al. (2006) are even more specific in relating cognitive processes to brain regions. They state that inferencing is accompanied by the activation of many regions in the brain. These regions act in consort, but building upon previous studies, Kuperberg et al. (2006) suggest that parts of this network may have distinct roles in causal inferencing. The temporal regions are involved in the activation of stored semantic information; the inferior prefrontal regions may mediate the retrieval and selection of semantic information; the posterior inferior prefrontal regions and posterior dorsolateral prefrontal regions may play a role in the maintenance of semantic information in working memory as it is integrated in long-term memory; activity in the superior medial prefrontal regions may reflect directed search for meaning and the examination of temporal relationships between events to generate inferences. Furthermore, they suggest that the activation in the right temporal and inferior prefrontal regions play a role in detecting incoherence in the discourse. These suggestions are speculative, but they indicate how imaging studies may advance theories about inference processes.

The neural correlates of discourse comprehension processes have only recently been investigated. This is a promising line of research. But we need more relevant empirical data, as well as

replications of earlier data, because consistency and convergence are important issues. This is particularly relevant since studies differ in many respects: the method, the task for the reader/listener, the materials that are used in the experiment. To illustrate this point: A topic of quite a few studies is coherence, including lack of coherence, coherence breaks, and inferences to establish coherence. Different studies find quite different locations of activations; they differ even with respect to whether there is activation in the left or right hemisphere. But that is not so surprising if one considers that under the guise of (in)coherence processing quite different operationalizations of coherence and quite different tasks are hid, that give rise to quite different cognitive processes.

In Mason and Just (2004), for example, coherence is operationalized as different degrees of causal relatedness between two consecutive sentences. Moderate coherence resulted in greater activation in specific areas of the right hemisphere (middle and superior temporal gyrus, inferior temporal gyrus, inferior frontal gyrus, and inferior parietal area). The task was to read the texts and to answer probe questions for filler texts.

Robertson et al. (2000), on the other hand, operationalized coherence as presence of a definite or an indefinite article. The indefinite article produced more activity than the definite article in the right hemisphere, in particular in the prefrontal region, but not in the left hemisphere. The task was to read sets of sentences.

Ferstl and Von Cramon (2001), for their part, operationalized coherence in terms of (un)related sentences. The task was to judge whether the two sentences have something to do with each other. They found that the coherence manipulation resulted in activation in the left frontal gyrus. They did not find any additional activation in the right hemisphere (see also Ferstl et al., 2008).

In Virtue et al. (2006a), coherence break is operationalized as a place in the text where an inference is required: A sentence had to be connected to the preceding sentence; in one condition an unspecific verb ('got to work') occurred in the preceding sentence, in the other condition a specific verb (started ironing). The task was to listen to the text and answer a question, not related to the coherence break. They found increased activation for the unspecific over the specific event in the right and left superior temporal gyrus and inferior frontal gyrus.

Kim et al. (2012) used strong coherence and weak coherence stories of three sentences in a positron emission tomography study. This technique, as fMRI, measures brain activity on the basis of local blood flow. The last sentence in the weak condition required an inference, but the last sentence in the strong condition did not. The task was to read the sentences and to judge the plausibility of the last sentence. In the strong coherence condition, the dorsomedial prefrontal cortex was activated relative to a control condition. This was interpreted as reflecting coherence processing (but in other studies activation at this location is obtained in low coherence conditions). In the weak coherence condition, the left middle temporal gyrus was activated. This was interpreted as reflecting a bridging inference.

The operationalization of coherence in these studies might very well lead to quite different cognitive processes. The use of indefinite articles in the Robertson et al. (2000) study violates (Gricean) maxims of conversation, in particular of referring. Moreover, some of the references are ambiguous. The reader has to deal with these problems. It is not very likely that establishing reference in this task is done on the basis of world knowledge activation. Quite different are the Mason and Just (2004) and the Virtue et al. (2006a) studies. In these studies, coherence can be achieved by activating world knowledge, making bridging inferences, and integrating them into the discourse representation. And indeed, Mason and Just argue that these processes take place and that they can be distinguished as located in different brain networks. In the Ferstl and Von Cramon (2001) study, participants perform a metalinguistic decision task. To reach a criterion that two sentences have nothing to do with each other, in comparison with the sets of sentences that are connected, it is not necessary that participants engage in world knowledge activation and inference generation, as in the Mason and Just study. Finally, in the Kim et al. (2012) study, the metalinguistic task of judging the plausibility of a sentence introduces an additional task and probably introduces additional processes.

The upshot is that different materials and different tasks may lead to different processes in coping with 'incoherence.' These examples illustrate the need for carefully conducted empirical studies on inference processes. Only then will brain studies increase the understanding of the different subprocesses in inferencing and how they are related to each other. Brain research will then not only reveal which areas in the brain are activated in specific tasks, but may also yield data that contribute to a theory of inferences and discourse comprehension.

Infertility: Demographic Aspects

Marida Hollos, Brown University, Providence, RI, USA

© 2015 Elsevier Ltd. All rights reserved.

This article is a revision of the previous edition article by U. Larsen, J. Menken, volume 11, pp. 7435–7439, © 2001, Elsevier Ltd.

Abstract

Infertility is a condition that affects individuals and couples in developing and industrialized countries alike. In developing countries, infertility is relatively high; it is predominantly secondary infertility (the inability to conceive or bear a second child), due to STIs. In industrialized countries, it is mostly due to delayed childbearing by which time women's fecundity has decreased significantly. Thus, it is usually primary infertility (the inability to conceive or bear a first child). In developing countries, not having a child is a devastating problem for women, particularly in the high fertility context of sub-Saharan Africa. Assisted reproductive technologies (ARTs) are few in developing countries and only affordable to a small portion of the population. ARTs exist in practically all the industrialized countries and are available to most women and are often subsidized. Voluntary childlessness, however, is growing in Europe.

Definitions

The clinical definition of infertility is the absence of conception after 12 months of regular unprotected intercourse. The World Health Organization (WHO) definition specifies a period of 24 months. Demographers define infertility as the inability of a sexually active woman who is not using contraception to have a live birth. Demographers have shifted the endpoint from conceptions to live births because it is difficult to collect complete data about conceptions in population-based studies.

Primary infertility is defined as the inability to have one child, and secondary infertility occurs when a woman who has borne at least one child is unable to have another. According to the demographic definitions, primary infertility is approximated by childlessness and secondary infertility by the proportion of subsequent infertility measured for women with children. The level of infertility in a population is usually measured by the proportion of reproductive age women who are infertile.

It should be noted that while these definitions are useful in Western settings and also allow for the comparison of cross-national or regional comparisons of fertility and infertility rates or across time, researchers who are interested in local meanings and perceptions of infertility try to utilize local definitions. For example, Leonard (2002) describes Chadian women's perceptions of fertility problems as including difficulty in proving one's fertility shortly after marriage, the loss of reproductive potential (through miscarriage, stillbirth, abortion), and bearing "too few children."

Developing Countries

Until recently, infertility as a public health or demographic concern has largely been neglected in developing countries (Inhorn and van Balen, 2002; Feldman-Savelsberg, 2002; Hollos and Larsen, 2008). It has been obscured by the high fertility rate of many regions, particularly sub-Saharan Africa, that gave rise to a "concern over population growth that is not conducive to the perception of infertility as a real problem" (Frank, 1983: p. 142). There is now an increasing recognition in demography and the social sciences in general that infertility is a devastating problem for women, particularly in the high fertility context of sub-Saharan Africa (e.g., Boerma and Mgalla, 2001; Inhorn and van Balen, 2002). Worldwide, an estimated 580 million people experience infertility at some point of their reproductive lives. Of these, about 372 million people reside in low- and middle-income countries. Africa shares the largest burden of infertility in the world (Okonofua and Obi, 2009).

Childlessness in a pronatalist society with high fertility rates has a great effect on women, as women have responsibility for social and biological reproduction (Gerrits, 1997; Sundby and Jacobus, 2001; van Balen and Gerrits, 2001; Cornwall, 2001; Silva, 2009; Hollos, 2003; Dyer, 2007). This is particularly the case in patrilineal societies, in which the father's family has sole legal rights over children.

To document the increased attention paid to the problem of infertility, the 1994 United Nations International Conference on Population and Development called for reproductive health rights that seek to provide women with the right to have the "capacity to reproduce and the freedom to decide if, when and how often to do so … and provide couples with the best chance of having a healthy infant" (United Nations, 1994: Section 7.2).

Following this attempt, the WHO Department of Reproductive Health and Research proclaimed that infertility is an 'unmet need' in family planning research and program initiatives (WHO, 2004). Since the WHO convened an international meeting on infertility in 2001, they have published several reports and papers regarding advanced reproductive technologies in developing countries, including widely disseminated guidelines on standards, glossaries, ethics, and even a laboratory manual on "standard reference values for human semen" (WHO, 1999).

The proportion of infertility in currently married women ages 25–49, in first union, married more than 5 years that are childless ranges from 1.7 to 2.5% in Asia, from 0.9 to 2.8% in Latin America, from 2.2 to 2.8% in North Africa, and from 0.9 to 2.3% in sub-Saharan Africa (Larsen, 2003). Secondary infertility is more variable but highest in sub-Saharan Africa,

due largely to the presence of a threatening, high prevalence 'infertility belt' stretching across Central Africa from Southwestern Sudan to Gabon. In some Central African populations, infertility problems occur in 30–50% of all couples attempting to conceive. As a result, the WHO sought to obtain baseline statistical information in country- and region-wide infertility prevalence patterns throughout the continent (WHO, 1987). Based on this data, Larsen (2000) estimated infertility for 28 countries that conducted world fertility surveys or demographic and health surveys between 1978 and 1997 in Africa. The most striking aspect of infertility in Africa is its wide variation, which can occur within as well as between countries. For example, according to the 1990 Nigeria DHS, approximately 4% of women aged 30 years and older have never borne a child. A recent population-based survey of women of reproductive age in Ile-Ife, Nigeria, however, revealed that up to 20% of women have secondary infertility (Snow et al., 1995). Other community-based data suggest that up to 30% of couples in some parts of Nigeria may have proven difficulties in achieving a desired conception after 2 years of marriage without the use of contraceptives (Adetoro and Ebomoyi, 1991).

There is also evidence (Larsen, 2003) that there is an increase with age in the African pattern of infertility, which is in part due to biological aging, but most of it must be attributed to disease. High rates of secondary infertility are attributed to very early initiation of sexual intercourse and sexually transmitted diseases. The primary infertility-causing diseases appear to be gonorrhea and chlamydia (Okonofua and Obi, 2009), which can, if untreated, lead to occlusion of the fallopian tubes. Evidence is accumulating that infertility today may be related to HIV infection.

The rates of infertility are variable even within the same region, and local levels and sociodemographic patterns of infertility have not been widely documented .There are a number of important studies, however, that focus on infertility in developing countries, most of them in Africa. Inhorn (1994) looks at the relentless quest by poor Egyptian urban women for remedies for their infertility. In a later work, Inhorn (1996) looks at gender relations and the importance of fertility/infertility in the context of patriarchy. Some other studies focus on different aspects of childlessness, including local perceptions of the causes of infertility, its social consequences, individual treatment seeking behaviors, and community-based mechanisms for dealing with barrenness.

Local perceptions of the causes of infertility are documented in a number of works. These include witchcraft and spirit possession (Kielmann, 1998; Upton, 1999; Ebin, 1982; Okonofua, 2003). Other locally imputed causes of infertility include sexual promiscuity by women (Upton, 1999; Kielmann, 1998), nonobservance of prescribed behavior (Ebin, 1982), blood incompatibility (Roth, 2001), abortion (Okonofua et al., 1997), and 'mchango' (Roth, 2001; Gijsels et al., 2001).

There is ample documentation on the social consequences of infertility for women, who bear the brunt of it, especially in Africa. As Inhorn (1994, 1996) has shown for Egypt, regardless of the medical causes of infertility, it is women who are ostracized, suffer personal grief and frustration, social stigma, and often serious economic deprivation. In the Cameroon, infertility is a cause for divorce (Feldman-Savelsberg, 1999) as it is in Nigeria (Hollos, 2003). Bodies of infertile women are buried on the outskirts of town among the Yoruba (Ademola, 1982) and among the Aowin in Ghana (Ebin, 1982). Fertility has been shown to be important in the progression of women through life stages and thus in the creation of their identity as mature persons (Hollos, 2003).

More recently, Hollos and her colleagues (Hollos and Larsen, 2008; Hollos et al., 2009) documented differences in the rates of infertility and the perception of the condition in two Nigerian communities. They found a relationship between community treatment of women and the historical prevalence of childlessness.

Industrialized Countries

It is not possible to provide accurate country level estimates of infertility in populations with widespread contraception. In these societies, fertile women historically had the number of children they wanted and subsequently used contraception to prevent further births. Nevertheless, several investigators in Europe provided a wide range of estimates of the prevalence of infertility, ranging from 6 to 20%. A population-based survey of infertility and subfecundity in Denmark, Germany, Italy, Poland, and Spain (Karmaus and Juul, 1999) found that the percentage of sterile women ranged from 7% in Denmark to 1.8% in Poland, with the rest of the countries between these figures. The proportion of sterile couples presented a similar profile, with Denmark at 9.3% and Poland at 2%. According to a report by INED (Sardon, 2000: p. 298) permanent infertility in Western Europe rose rapidly among the post-World War II cohorts and has topped 20% since the 1960 cohorts in England and Wales, 1963 in Austria and Italy, and 1965 in Finland and Ireland. Portugal's rate remained low at under 8% of infertile women.

In the United States, estimates from a large national sample suggest that 10–15% of nonsurgically sterile American women ages 15–44 experience fertility problems (Chandra and Stephen, 1998).

According to Philipov and Dobritz (2002) involuntary infertility in Eastern and Central Europe has risen during the preceding years. Before the start of the political transition, infertility was close to the average level observed in Western Europe, around 6%. During the 1990s, it increased in many countries of the region. A study by Philipov (1998) indicates that in Western Siberia, 16.7% of the couples could not achieve pregnancy for at least 12 months; 3.8% of the couples suffered from primary infertility and 12.9% from secondary infertility. The Bulgarian Association of Sterility and Reproductive Health states that infertility is between 9 and 15.3% in that country. In the Czech Republic, it was found to be 12%, in Romania in 1999 it was 11.0%, and in Ukraine 10.6% (Philipov and Dorbritz, 2002: p. 123).

There is persistent fear that infertility in industrialized countries is increasing even further. There are a number of factors accounting for this trend, most important of which is the increasing delay in childbearing. Whereas previously women had their children at younger ages, currently there is a delay in childbearing, which means that more women are hoping to have a child at older ages when their fecundity may

have declined. Kohler et al. (2002) call this a "postponement transition," i.e., "a shift from an early to a late pattern of first birth" (Sobotka, 1989: p. 280). This increase in the mean age at the birth of the first child increased suddenly and significantly by about 1.5–2 years toward 2000. The rise in age was steepest in the ex-Yugoslav countries, the Czech Republic, Hungary, and the Slovak Republic. Western European countries have experienced a similar rise in the mean age at first birth. Births of the first child decreased significantly. This secular trend toward later childbearing has contributed to the decline in period fertility rates. The total fertility rate (TFR) Europe wide of first order births was around 0.9 and higher before the start of the transition, thus indicating universality of the birth of at least one child. Toward the end of the 1990s, the rate dropped below 0.9. According to Philipov (2003) this trend indicates a break in the universality of having children. Voluntary childlessness came on the rise, as well as a rise in the infertility rates of individuals who did desire children.

The reasons for the postponement and subsequent declining birth rates predominantly reflect social and economic factors that are to a large degree voluntary. These social and economic factors include an expanded role for women in the workforce, higher educational opportunities for women, as well as the availability of modern contraceptives and safe and legal abortions. The result of these social and economic trends is that women in industrialized countries suffer predominantly from primary infertility.

A consequence of the delay in childbearing and the difficulty of conceiving is the growth of assisted reproductive technology clinics in Europe, Australia, and New Zealand, and in the United States. Following is a brief summary of the results generated from European registers by the European Society for Human Reproduction and Embryology (ESHRE) and published in 2006. This is the tenth annual report. Reporting began in 1997.

Data in 2006 was collected from 32 countries, up from 26 in the previous year covering *in vitro* fertilization (IVF), intracytoplasmic sperm injection (ICSI), frozen embryo replacement, egg donation, *in vitro* maturation, pooled data on preimplantation genetic diagnosis, and frozen oocyte replacements. The number of clinics in the various countries ranged from 1 (Latvia, Iceland) to 202 in Italy, 182 in Spain, 122 in Germany, and 102 in France. The number of treatment cycles in total was 458 759, 40 648 more than in 2005. The distribution of clinics according to the number of cycles varied considerably among the countries. For example, in Italy, 46% of the clinics provided fewer than 100 cycles annually, whereas in Belgium and Sweden, 50% of the clinics performed more than 1000 cycles a year. In the Netherlands, 62% of the clinics performed more than 1000 cycles annually. The largest number of assisted reproductive technology (ART) cycles was reported from France (66 000), Germany (55 000), Spain (50 000), the United Kingdom (44 000), and Italy (42 000). None of these reach the number of reported cycles from the United States (138 198). Australia and New Zealand reported 53 543 cycles.

The average number of treatment cycles per million inhabitants ranged from 122 in Latvia to 2268 in Denmark. ART cycles in women of reproductive age (15–49 years) also show large differences from 475 cycles per million women in Latvia to 10 132 in Denmark. The percentage of newborns conceived through ART varied from 0.8% in Montenegro to 4.1% in Denmark.

The age distribution of women treated with IVF varied across countries. In several countries, more than 20% of women were aged 40 years of more (Greece, Ireland, Italy, Macedonia, Montenegro, Serbia, and Switzerland), whereas it was less than 10% in Bulgaria, Czech Republic, Lithuania, Poland, Norway, and Ukraine. As expected, pregnancy rates declined with age. Pregnancy rates in Europe remain lower than in the United States where 35% of cycles from nondonor cycles resulted in pregnancy. However, pregnancy rates in Europe are very similar to what is achieved in Australia and New Zealand where the pregnancy rate per transfer was 30.6% after fresh cycles and 21.5% after frozen embryo transfers.

In summary, the ESHRE report shows a continuing expansion of clinics and treatment cycles. Pregnancy rates from IVF and ICSI showed marginal increases compared with 2005.

Childlessness

Childlessness is an important and growing phenomenon and has increasingly become the focus of research by sociologists and policy makers, primarily in Western Europe. As McAllister and Clarke (2000: p. 189) point out, "as the average age of motherhood has increased in many Western societies, the issue of distinguishing between those who postpone parenthood and those who renounce it altogether has become of key interest."

Historically, childlessness is not new. It was quite common until the early part of the twentieth century. According to Wrigley and Schoefield (1983), in eighteenth-century England, up to one quarter of women remained unmarried and the majority of these had no children. However, in the past, childlessness among married women was primarily due to poverty and consequent malnutrition. Childlessness today (see, for example, Dykstra and Hagestad, 2007), while similar in magnitude, is very different from the past. It occurs among healthy, sexually active women who live in relative prosperity.

The prevalence of lifetime childlessness has been shown by demographers to be far from uniform both within and between countries, and according to Coleman (1993), it is likely to generate considerable differences in fertility levels. While exact figures are difficult to obtain, many sources provide differing estimates and projections of current trends suggesting that in many countries from one-fifth to one-quarter of women will remain childless throughout their lifetimes (Eurostat, 1997; Morgan and Chen, 1992; Coleman, 1998; Rowland, 2007). In addition to Germany, England and Wales, Canada, Finland, and Austria, this includes various Eastern European countries (Coleman, 1998). Researchers agree that primary infertility cannot account for this level of childlessness (Rindfuss et al., 1988; Ruthstein and Shah, 2004; Vaessen, 1984).

Evidence from a number of studies (Veevers, 1983; Campbell, 1985; Gerson, 1985; Morell, 1994; Beets, 1995) suggests that there is fluidity to being childless. Decisions about childbearing may be very different at younger ages than toward the end of a woman's reproductive years (McAllister and Clarke, 2000). While the desire to have children at younger

ages may be stronger, the postponement of first births may result in increasing fertility problems after age 35; and delaying the decision to have children may lead to infecundity. Campbell (1985) and MacInnes (2006) also argue that becoming childless is a process and that many couples may 'drift' into childlessness through postponement. However, an analysis of fertility intentions, using Eurobarometer data, shows that across Europe there is a large variation in the intention to remain childless. This may, of course, depend on cultural values and norms regarding parenthood (Bernardi, 2005). The 1996 Italian Fertility and Family Survey, for example, suggested that "childlessness, rather than being driven by deliberate choice, was an outcome of a series of life circumstances that were beyond women's control" (Bonarini et al., 1999).

Conclusion: Two Worlds of Infertility

As shown in the previous discussion as well as in a review of recent literature on infertility by Greil et al. (2010), there are salient differences in the experience of infertility between developing and industrialized societies. They propose that it may be justifiable to think in terms of two worlds of infertility. Developing and industrialized countries tend to differ in prevailing assumptions about childlessness.

In industrialized societies, voluntary childlessness is viewed as a viable legitimate option and women without children are often assumed to be voluntarily childfree. However, in developing countries, having children is central to women's role in society. The option of voluntary childlessness does not exist. In these societies, it is impossible to hide infertility.

Another difference between infertility in developing and industrialized societies has to do with folk models for making sense of the condition. In industrialized societies, the acceptance of the biomedical model is hegemonic, while in other societies biomedical interpretations of infertility coexist and interact with traditional interpretations.

Finally, ARTs are widely available in industrialized countries and are few and mostly beyond the reach of individuals in developing countries.

Abstract

This article presents estimations of the shadow economies of 17 OECD countries, 21 developing countries, and 14 transition countries for the mid-1990s and mid-2000s. Additionally the reasons why people work in the shadow or underground economy are presented. Also the effect of the underground economy on the official economy is discussed and the presence of a shadow economy tends to overestimate the inflationary effects from a fiscal or monetary stimulus, and tends to understate the respective effects on unemployment. Finally, policy consequences are shown. One major result is that a positive approach to raise the motivation to stay in the official economy by improving the efficiency of public services, reducing the tax and social security burden and/or by raising the civic virtue, has been used only rarely, but is a highly efficient policy tool.

There is a widespread feeling that the underground economy is of substantial size and, compared to the official economy, has been growing rapidly. This holds in particular for developing and transition economies, but also for developed economies. The major concern is that government revenue is thereby lost and the cement of society is undermined. On the other hand, underground economies are value-creating and introduce a dynamic element into the economy. The underground economy is variously defined, but the predominant definition is to comprise all at present not officially recorded productive (i.e., value-adding) activities, which should be part of gross national income. This definition excludes activities not in the gross national product (GNP) (e.g., housework), and it is not identical to tax evasion (which is mostly redistributive) nor to illegal activities (some activities are legal but not subject to taxes, and therefore tend to escape being recorded). Economists have devised a considerable number of approaches to measure the size of the underground economy. The direct approaches are based on surveys and the examination of tax returns. The indirect approaches analyze the discrepancies between what would be 'normal' and what is actually observed with respect to spending, employment, the use of money, and physical input (such as electricity).

A more refined approach constructs a model identifying the incentives to work in the underground economy: the burden of taxation and social security contributions, expected punishment, and the moral cost of being active in the illegal economy. Empirical estimates of the size and the development of the underground economy relative to official recorded GNP are presented for developed, transition, and developing economies. In most countries and periods, the underground economy has been negatively evaluated and therefore considerable efforts have been expended in fighting it. Most policies seek to increase deterrence by stepping up controls and raising punishment, often with doubtful success. More promising policies are to lure people from the underground economy into the official economy by legalizing part of the respective activities, improving the efficiency of public services and the relationship of the state to its citizens, thereby raising civic virtue, and thus reducing the incentive to work in the underground economy.

There is a widespread feeling that a substantial and increasing share of value-creating activities take place outside the official economy. This holds, in particular, for developing and transition economies, but also for high-income economies. Such activities are not recorded by the system of national income accounting, which has become the accepted standard in all countries of the world.

The existence and increase of an underground economy gives rise to four major sets of concerns. The economic and social conditions of individuals, households, and countries are evaluated in a biased way if one relies on the official statistics. Thus, the official number of unemployed persons may hide that a (unknown) share of them actually work and receive wage income. As a consequence, the macroeconomic policies are likely to be too expansionary and social policy too excessive. A second concern is the loss of tax revenue, as underground activities escape taxation. A third concern interprets the underground economy as an indicator of an unhealthy relationship between citizens and government. The taxpayers are dissatisfied with the public services they get for their contributions and seek to redress the balance by escaping to the underground economy. It is feared that such a reaction makes a government unable to finance the public goods necessary for an economy and society. A fourth concern goes even further, and fears that an underground economy undermines the cement of society because it favors everyone acting in his or her own interests, while solidarity is renounced. In contrast to these concerns, the existence of an underground economy has also been seen in a positive light. Opponents of extensive state activity welcome the limits imposed on taxation and regulation, and applaud the dynamism and flexibility in the underground sector.

Denominations and Definitions

The phenomenon is known, and has been discussed in literature, under many different names: informal, unofficial,

irregular, parallel second underground, subterranean, hidden, invisible, unrecorded, and shadow economy or moonlighting. In several languages, the term most often used is 'black economy' ('le travail au noir' in French, 'Schwarzarbeit' in German, and 'svarta sektor' in Swedish).

No single definition exists, but it depends on the purpose. The most precise and predominantly used definition seeks to relate the underground economy to officially measured national income: it comprises all presently not recorded productive (i.e., value-adding) activities which should be in the GNP. This definition allows us to compare and to add the underground economy to GNP.

This definition excludes two major activities:

1. Production that by convention is not part of GNP, in particular private household activities. The evaluation of its size has engendered a research area of its own. Depending on the approach and measurement technique in developed economies, the household sector comprises between 30 and 50% of GNP.
2. Tax evasion is not value-adding but redistributional and is therefore not included as such in the above definition (e.g., when taxes on interest payments are evaded). However, in general, no taxes are paid on underground activities (such as moonlighting for house building) which are value-adding. Thus, underground activities and tax evasion are related, but certainly not identical. Tax evasion has also become a research area of its own. For the United States, between 1973 and 1992 for example, it has been estimated that 17 of total taxes owned have been evaded.

The underground economy should not be identified with illegality. Some activities are perfectly legal but are not subject to taxes (e.g., because of their small size), and therefore escape measurement in official statistics. Other activities are legal as such, but taxes are evaded. Finally, on illegal activities (such as drug production and distribution), no taxes are paid.

Broader definitions of the informal and underground economy, depending on their purpose, include private household production and redistributional activities. In the following, the more narrow definition considering unrecorded productive activities will be focused on.

Measurement Approaches

The major effort of economists has been to measure the size of the underground economy relative to official GNP; its size compared to other countries, and its development over time. The other social sciences, especially sociology, have put more emphasis on the structure: who participates where? The respective studies often provide highly detailed analyses of particular regions, industries, and types of underground activities. A considerable part (it varies strongly from country to country) of informal activity is undertaken as a second job and part-time. This allows underground workers to be eligible for social security benefits and makes detection more difficult. Not surprisingly, casual work is dominant (if not the only kind of work) for illegal immigrants. In developed economies, casual work is most prevalent in the following sections: in agriculture (especially seasonal labor), in construction, and in the services sector, particularly in repairs (automobiles and other) and cleaning, in hotels and restaurants, as well as in wholesale and retail trade. Accordingly, among the occupations with most illegal work are cleaning persons, waiters, people working at home, and construction and mechanical workers.

In the 1980s and 1990s, the quest to measure the size of the underground economy led to interesting methodological innovations, i.e., the challenge to 'measure the invisible' resulted in new measurement methods. Three general sets of measurement approaches can be distinguished.

Direct Approaches

An obvious way to analyze the underground economy is to undertake surveys among (supposed) suppliers and demanders of casual services. This method allows us to gather a detailed picture of the structure of this sector. However, because a substantial part of these activities is illegal, the interviewees may not be prepared to disclose their involvement. Somewhat surprisingly, research suggests that disclosure is not a serious problem. Typically, men are more involved in the underground economy than women, the young more than the old, people without work more than employed people, and the most prominent sectors are construction and all kinds of services. In contrast, where substantial capital assets (which are visible) are needed, less underground activity is observed.

A second direct approach is based on auditing of tax returns undertaken by tax collection and social security administrations. A sample of tax-payers is scrutinized in depth and under threats of sanctions for failing to collaborate. This approach provides detailed information on the biggest evaders, in particular the self-employed, who have better opportunities for concealment. Capital income also lends itself easier to evasion than labor income. Tax audits have proved unable to reveal all tax evasion, and are limited to taxable activities. As a large part of tax evasion is redistributional, that part is not relevant to the narrow definition of the underground economy.

The two direct methods (surveys and tax auditing) have the disadvantage of permitting point estimates only. Moreover, it is unlikely that they capture all 'shadow' activities, so they can be seen as providing lower bound estimates. They are unable (at least at present) to provide estimates of the development and growth of the shadow economy over an extended period of time. They have, however, one considerable advantage – they can provide detailed information about shadow economy activities and the structure and composition of those who work in the shadow economy.

Indirect or Discrepancy Approaches

The underground economy is reflected in discrepancies showing up in various markets. Persons working in the unofficial sector are able to *spend* more than their officially recorded income. The discrepancy between the two may be observed at the level of individual households, as well as in the aggregate national accounts. This approach is questionable, as this expenditure–income discrepancy may either be due to measurement errors (which is indeed often the case) or to reasons unrelated to the underground economy (e.g., the use of credits, or reductions in wealth).

Another discrepancy may be observable in the *labor market*. A decline in official participation rates, or a low participation rate compared to other countries, may be an indication of unofficial work. But again, the discrepancy may be related to other factors. Moreover, this approach is unable to isolate those persons who are at the same time active in the official and the unofficial economy (which seems often to be the case, according to other approaches).

A third discrepancy may be visible in the *monetary market*. The dominant approach starts with the assumption that underground transactions are paid in cash in order to make detection more unlikely. The size of the underground economy is reflected in the amount of cash used in a country beyond that used for official transactions. This approach is elegant and easily applicable because the amount of currency is well documented. The assumption that unofficial activities are transacted in cash is, however, questionable. Empirical research suggests that between 20 and 30% of the unofficial activities are not paid in cash, i.e., either by payment in kind or via a bank. This fact is especially bothersome for the currency demand approach when the share of cash payments changes over time and differs between countries. A significant portion of some currencies is held outside the country issuing it; thus the US dollar is widely used in South America and Asia. Again, the discrepancy is influenced by many factors unrelated to the underground economy, such as the use of credit cards. Finally, it is problematic to infer the size of the unofficial sector from currency transactions, because the velocity of cash circulation may differ between the official and the unofficial sector. Some of the difficulties just mentioned have been successfully addressed by more recent research. Thus, the use of credit cards and the amount of currencies outside a country have been taken into account. Most importantly, instead of comparing the actual use of cash to the one deemed necessary for the official economy, a cash demand function is empirically measured, i.e., econometrically estimated. This allows us to check for influences (such as changes in the interest rate or the increasing use of cash substitutes) unrelated to the underground economy. Moreover, the extra use of cash has been directly attributed to causal factors, in particular to an increase in the tax and social security burden. Figures for the size and development of the shadow economy can be calculated by comparing the difference between the development of currency when the direct and indirect tax burden and government regulations are held at their lowest value, and the development of currency with the current (higher) burden of taxation and government regulations. The currency demand approach is one of the most commonly used approaches.

The most recent discrepancy approach looks at *physical inputs*, in particular the use of electricity. How much electricity would normally be used to produce the official national income is calculated. The excess use can be attributed to the underground economy. This approach again has the great advantage of relying on easily available data, which is a distinct advantage for developing and transition economies. However, not all underground activities use much, if any, electricity, and the relationship between production and electricity used may change over time, or differ between countries, due to substitution and technical progress.

A general problem of all discrepancy approaches is that one has to assume a base year without underground economy. Only then is it possible to attribute the existence and rise of a discrepancy to the underground economy.

The Model or Multiple Indicator and Multiple Causes Approach

This method focuses on the causes and effects of the underground economy. By constructing a model, it seeks to identify the unobserved sector in between.

Three sets of factors are taken to be the main motivators of whether to engage in the unofficial economy:

1. The burden of taxation and social security contributions as well as government regulations provide incentives to exit the official economy. The latter hinder or even prohibit activities in the official economy (e.g., because of lacking work permits, especially for foreigners), which provides an incentive to undertake them unofficially. This holds, of course, also for illegal activities such as the production and distribution of drugs. An important reason for exiting the official sector is the restrictions imposed on working time. Low work hours, long holidays, early retirement, and, above all, unemployment, are important reasons for moonlighting.
2. The expected punishment of working in the underground economy provides a disincentive for doing so. It consists of the probability of being caught and the size of punishment. For persons outside the established society (for example, illegal immigrants), or for self-employed persons, expected punishment is lower than for other persons, and therefore a higher rate of participation in the underground sector is likely.
3. The moral costs are another disincentive to be active in the underground economy. A good citizen has moral qualms about undertaking a forbidden activity. These moral costs are closely related to 'tax morale' which motivates citizens to pay their dues to the state.

The effects of the underground economy are reflected in the traces visible in the labor, money, and product markets discussed earlier. A specific econometric technique called 'unobservable variables approach' allows us to estimate the size of the underground economy. This technique seeks to identify the size of the underground sector, which cannot be observed itself, but whose causes (e.g., tax and social security burden, unemployment) and whose effects (e.g., fall in the participation ratio) can be measured. This approach is the most comprehensive and builds on a well-structured behavioral model, but it requires a large amount of data. As these are often not available (in particular not for developing and transition economies), this approach is not generally applicable over a long (extended, 30 years) period of time; for 162 countries data are available over 1999–2008. The estimation technique moreover tends to be statistically fragile (i.e., small changes in specification and values of variables affect the estimates).

Empirical Estimates

The following tables serve to indicate approximate magnitudes of the size and development of the underground economy, defined as productive, value-adding activities, which should be

part of GNP. Table 1 presents a rough comparison of the size of the underground economies relative to GNP for a selection of Western European countries, Japan, and the United States for the mid-1990s, using the currency demand approach and for the mid-2000s the Multiple Indicator and Multiple Causes (MIMIC) approach.

The South European countries (Greece and Italy) have an underground economy almost one-third as large as the officially measured GNP: followed by Spain, Portugal, and Belgium, having a shadow economy between 20 and 24% of (official) GNP. According to these estimates, the Scandinavian countries also have a sizable unofficial economy (between 18 and 20% of GNP), which is attributed mainly to the high fiscal burden. The 'central' European countries (Ireland, The Netherlands, France, Germany, and Great Britain) have a smaller underground economy (between 13 and 16% of GNP), probably due to a lower fiscal burden and moderate regulatory restrictions. Smaller underground economies are estimated to exist in countries with relatively low public sectors (Japan, the United States, and Switzerland) and comparatively high tax morale (United States and Switzerland).

Table 2 provides a rough comparison of the size of the underground economy relative to official GNP for a selection of developing and transition economies for the beginning of the 1990s, using the physical input (electricity) demand approach and for the mid-2000s the MIMIC approach. Some of these countries (Nigeria, Egypt, and Thailand) are estimated to have an underground sector nearly three-quarters the size of officially recorded GNP. In many countries, the size is one-quarter to one-third of GNP. In Asian countries, with a comparatively low public sector, high tax morale, or high expected punishment (Hong Kong, Singapore), the underground economy is estimated to be similar to that in many 'Northern' European countries.

Transition economies are estimated to often have substantial unofficial activities, many around one-quarter of GNP. An exception is ex-Czechoslovakia where, according to these estimates, the underground sector is clearly around 10% of GNP.

Table 1 Size of the underground economy relative to GNP in various OECD countries, mid-1990s (estimation based on the currency demand approach for the mid-1990s and the MIMIC method for the mid-2000s)

	Mid-1990s	*Mid-2000s*

Table 3 reports estimates of the growth of the underground economy (relative to GNP) for selected Western countries and the United States, using the currency demand and the MIMIC approach.

The Scandinavian countries (Sweden, Norway, and Denmark) and the German-speaking countries (Germany and Austria) exhibit a sizable increase of the underground economy within the 35 years covered (1960–95) and tend to understate the respective effects on unemployment. Also the countries with a low share in the beginning (Switzerland and the United States) show a significant increase, with the US share more than doubled. Sizable increases have been estimated, with few exceptions, for all types of countries and all kinds of approaches: the increasing importance of the underground relative to the official economy is a robust phenomenon. It has been attributed to many different causes, but the most important and most often cited ones are the rise in the burden of taxes and social security contributions, the increase in public regulations, especially on labor markets, as well as a long-term fall in civic virtue in the population.

The Effects of the Underground Economy on the Official Economy

In order to study the effects of the underground on the official economy, the underground economies have been integrated into macroeconomic models; this yields an extended macromodel of the business cycle, as well as tax and monetary policy linkages with the shadow economy. As a result, it becomes clear that these effects should be taken into account for tax and regulatory policies. The presence of a shadow economy tends to overstate the inflationary effects of a fiscal or monetary stimulus and tends to understate the respective effects on unemployment. When the growth of the shadow economy and the 'official' economy are positively related (which is likely to be the case when entry costs into the shadow economy are low due to a low probability of enforcement), an expansionary fiscal policy has a positive stimulus for both the formal and informal economies. It has also been found that the US productivity slowdown over the period 1970–89 was vastly overstated, as the under-reporting of income, due to the more rapid growth of the US shadow economy during this period, was disregarded.

The underground economy is beneficiary insofar as it responds to the economic environment's demand for urban services and small-scale manufacturing. The casual sector provides the economy with dynamic and entrepreneurial spirit and can strengthen competition, increase efficiency, and put effective limits on government activities. The casual sector contributes to the creation of markets, increases financial resources, and transforms the legal, social, and economic institutions necessary for accumulation. Moreover, a substantial part (up to 70%) of the earnings gained in the shadow economy is quickly spent in the official sector and thus boosts the official economy. These expenditures tend to raise consumer expenditures as well as (mostly indirect) tax revenues.

Policy Consequences

The growth of the underground economy over the few last decades and its effect on the official economy, both in general perception and scholarly research, has prevailingly been evaluated as a negative development, which should be counteracted. In particular, politicians and public officials have pointed out that the state's capacity to provide the desired public services is undermined because tax revenue is lost. But not all commentators share this view. Some see it as a welcome and effective limit on the tendency of governments to continually raise the fiscal burden and to impose more and more bureaucratic restrictions on the economy and society. More generally, the rise of the underground economy is interpreted to indicate that the relationship between the state and the citizens is fragile and needs improvement. It has also been argued that many developing and transition economies would break down or function at a much lower level of production and welfare if the underground economy did not exist.

The fight against the underground economy is a recurrent theme in many countries. The dominant method is to increase deterrence. The probability of being caught is raised by more regular and intensive controls, often by the police. Punishment is raised by imposing higher fines and, in severe cases, prison sentences. Both consumers and suppliers of goods and services produced in the underground sector are targeted.

The success of such deterrence policies is rather doubtful. In the case of the underground sector related to drugs, prostitution, and alcohol prohibition, the effect has turned out to be at best weak, if not counterproductive. Many persons active in the underground economy move more deeply into illegality in order to make detection more difficult. As a result, the underground activities become more criminalized, and more difficult to observe and to influence. Well-organized and ruthless, organized crime (often called the Mafia) becomes more dominant.

A deterrence policy need not always be a failure, but the successes tend to be short run. Provided the demand for

underground goods and services remains intact, the profit opportunities in the underground economy become so large that supply reappears and the underground economy recuperates. A less oppressive policy is to lure people into the official economy by legalizing parts of the underground economy, and by facilitating the move into the official economy (e.g., by granting an amnesty). Such measures have proved to be only moderately successful.

A positive approach to raise the motivation to stay in the official economy by improving the efficiency of public services, reducing the tax and social security burden imposed on labor, and/or by raising civic virtue has been used only rarely. Many policy makers doubt whether such measures work at all. In any case, they are effective only in the longer run. One possibility is to adjust public supply more closely to what the citizens desire, and to lower cost for a given quantity and quality of public supply. This can be attempted by streamlining public sector activities (e.g., by New Public Management). A more fundamental way is to improve the political process by opening the political arena to contending interests, and by strengthening the democratic participation rights of the citizens.

Abstract

A processual notion of informality is replacing that of an informal sector, which emerged in the early 1970s from research on urban development as a name for activities and enterprises escaping formal economic regulation. It and other terms for nonregulated economic activities have since then been applied to research in the West, yet the bulk of work continues to be undertaken in the developing world. Characterizing organizational processes as informal recognizes complex linkages between informal and formal activities across all economic levels rather than within clearly bounded sectors. The focus has changed from descriptions of informal activities in different settings to questions about their potential for growth to the dynamics of informalization in general.

Meanings of 'Informal'

In social science scholarship since the early 1970s, including policy research and development economics, and in applied work, the term 'informal' has been used variously for a segment of the labor market, a set of activities, a nonregulatory status, a form of insertion in labor markets, a type or size of firm, self-constructed housing, and a general characterization of the economy.

Although the notion of an informal sector was new, the activities to which it referred were not. Many had long histories in the West as well as the developing world. In effect, in the 1970s, the notion of an informal sector gave name to economic activities that generated income for large portions of urban populations in developing countries. With the unprecedented increase of urbanization in the developing world since the opening decade of the twenty-first century, more than half of the populations of many of these cities make a living and obtain shelter informally. Such processes represent persistent rather than provisional forms of urbanism, and they have complex links with the rest of the city, the region, and the global economy.

Informality: Sector or Process

In the early 1970s in field research among migrants in Accra, Ghana, Hart coined the term 'informal economy' (1973), contrasting their economic activities to formal, contractual wage labor. Since then, the informal sector has been a subject of extensive debate and research. The term 'informal' is more of a residual notion than a concept, defined in relationship to something else, that is, to what it is not. The chief questions raised in this scholarship concerned the content, structure, and dynamics of the informal sector, that is, what to include and exclude, how precisely to differentiate it from the formal sector, and what growth potentials it might have. Some scholars suggested alternative terms and frameworks, such as casual work, petty commodity production, or householding and provisioning (Bromley and Gerry, 1979). In francophone scholarship, informality is often referred to as *systeme D* (from *l'economie de la debrouillardise*), meaning self-reliance or do-it-yourself. Still, the 'informal sector' notion continues to be widely used for lack of any better descriptive term.

Despite their conceptual misgivings, most scholars agree that discussions about economic life must take account of informal economic development in its relationship to wider economies. For example, MacGaffey (1991) found informal activities to be so central to efforts at making a living in Zaire (now the Democratic Republic of Congo) during the last half of the 1980s that she characterized them as the 'Real Economy.' The idea of 'popular' or 'informal economies' is another way of highlighting the pervasiveness of nonregulated economic practices, recognizing their overall importance (Guyer et al., 2002). Thinking processually about 'informalization' avoids the arbitrariness of sectoral dichotomies (Hansen and Vaa, 2004). It also helps bridge the conceptual gap between production and reproduction, directing attention to household strategies and the ways in which household composition, stage of development cycle, and the gender and age of members introduce cultural assumptions into the division of labor. Women and children are highly visible segments of many informal markets, and development practitioners and human rights groups have recently begun to pay attention to the relationships of age and gender to informal sector developments, specifically with regard to trafficking and forced labor.

The 'Informal Sector,' Urbanization, and Development

Research into informal economic development in the developing world has clustered around several specific policy approaches aimed at promoting economic growth. The first cluster of work was influenced by Hart's (1973) research among migrants in Ghana that identified an 'informal economy' of self-employment, which was legitimate yet illegal, as opposed to regularized wage labor. International development agencies were at this time concerned about the failure of industrialization efforts to improve economic growth. Hart's observations were quickly absorbed into development policy directed at satisfying basic needs by harnessing informal income opportunities. In the International Labour Office's (ILO) Kenya mission, for example, such activities were explained as 'a way of doing things' (ILO, 1972), characterized by ease of entry, reliance on indigenous resources and family ownership, smallness of scale,

 http://dx.doi.org/10.1016/B978-0-08-097086-8.12094-X

being labor intensive with adopted technology, using skills acquired outside the formal school system, and participating in unregulated and competitive markets. Here, as elsewhere in the developing world, governments were encouraged to take a positive role, ceasing to demolish unauthorized housing, changing trade and licensing procedures, and providing technical and outreach support to informal sector activities.

The second cluster of work appeared in the wake of the International Monetary Fund's (IMF) structural adjustment programs, particularly from the late 1980s onward. Many of the policy measures (e.g., employment entrenchment in the public and private sectors; the introduction of value-added taxes; the removal of subsidies on food, fertilizer, and housing; and the introduction of user fees in schools and hospitals) advocated by the IMF and World Bank to transform state-controlled economies into market economies had adverse effects on already vulnerable groups. In fact, the volume and differentiation of informal sector activities increased during the 1980s. Strapped for revenue and burdened by accelerating international debt, many governments began encouraging interventions by local and external nongovernmental organizations (NGOs). The centerpiece of this renewed policy attention is 'microenterprises' and their enhancement through credit arrangements and the provision of basic training in technical skills. Perhaps more than any other scholar, King (1996) has documented, with rare longitudinal insights, the local effects of these changing policy interventions on the actions and achievements of informal sector artisans in Kenya.

Some observers who were disenchanted with the lackluster government performance in developing countries over previous decades viewed informal sector activities as examples of free market initiatives. The third, and more recent, approach to informality is represented by de Soto (1989, 2000), who offers a vision of informal entrepreneurship akin to heroism with people spontaneously and creatively responding to the state's inability to deliver basic services. In this view, legalization will enable people to secure and trade their assets, thus becoming part of the formal system. Property ownership, according to de Soto, will lift people from poverty. Attractive to the World Bank and some development agencies, de Soto's thesis has not found much empirical support.

The 'Informal Sector' and the West

While visually evident in streets and markets in developing countries, informal economic activities take place everywhere. Throughout most of the West today, small-scale enterprises that bypass official regulation and use off-the books labor practices put people to work providing goods and services (Portes et al., 1989). In some regions of the United States, such activities are associated with immigrant communities, whereas in parts of Europe, for example, they are based on long histories of artisanal enterprises and putting-out systems (Mingione, 1991). In the second or parallel economies of the former socialist countries in Eastern Europe, producers and consumers supplied, swapped, and bartered goods and services to alleviate market shortages, avoiding the bureaucratic bottlenecks of centrally planned economies. Also, informal sector activities in the West are not exclusively associated with a bygone era of economic history but keep reappearing in different places, operating in a variety of politico-economic contexts along with globalization (Sassen, 1998).

Policy Concerns

Since the turn of the last millennium, informality has come back on the agenda of international development organizations, urban planners, and researchers. In the renewed attention to informality, definitional issues continue to be debated as they have important implications for the identification of target groups and types of intervention. If the informal sector provides an economic safely net, it does so in different ways, depending on the type and level of activity, the resources brought to bear on its operation, and the local cultural context that shapes the participation of actors (Rakowski, 1994). Whether a growth potential in fact exists requires understanding of the nature both of the activities in question and of the social relations that structure them. In addition, the growth potential is not only a technical challenge or problem for urban management but also, in many places, a complex political struggle that provokes the use of force and violence.

Some researchers and development organizations avoid definitional discussions by using descriptive terms like 'microenterprises' and highlighting the role of informal networks in creating social capital. But microenterprises encompass a range of activities that draw on widely diverse access, require different types of resources and inputs, and, above all, put the young and the old and women and men to work on unlike terms. While some microenterprises may well contribute to economic empowerment and popular political participation, many others may fragment into networks of accumulation and survival that marginalize the efforts of the very economic actors who are pursuing them (Meagher, 2010).

Unless the economic and social nature of informal economic activities is accounted for in more specific terms, development assistance risks being restrictive, thus jeopardizing the very goal of expanding employment and income generation that it seeks to promote. Anticipating that persons with few means may forfeit loans, some credit programs, for example, target better-off participants, in this way accentuating already existing socioeconomic differentiation rather than reducing it.

Policy planning by government agencies and development organizations easily excludes informal economic activities because of their very nature: unregulated, always changing, and often mobile. Assessing their scale and scope is difficult because of the lack of comparable statistical information with which to document and analyze the characteristics of activities, enterprises, their built environment, the institutional or organizational context in which they operate, as well as the needs of their participants in terms of gender and age. In recent years, participatory and bottom-up approaches have begun to play local and transnational roles in mobilizing poor urban residents with regard to informal economic activity and informal housing. The mapping and documentation by residents of informal settlements may help to give them a voice in

lobbying, for example, about water, sanitation, and land issues. Being counted and showing that you have an address are part of the rhetoric of claiming a right to the city by populations who tend to be ignored (Patel and Baptist, 2012). Across the global urban South, such community-led exercises are sometimes linked with the establishment of local savings groups, and peer exchanges with the support of local and transnational NGOs (Lindell, 2010).

The Market Meets the 'Informal Economy'

Since the term 'informal sector' was coined in the early 1970s, the economic and political contexts in which research on this topic first emerged have changed. Shifts in the global economy are altering production processes in an international division of labor that is affecting both the industrial West and the developing world, but differently so. Neoliberalism in both politics and markets almost everywhere is giving rise to new research questions concerning the experiences of ongoing transformations. Socioeconomic differentiation has increased, juxtaposing wealth and poverty in new forms of inclusion and exclusion that are conspicuous in the urban-built environment: gated communities and upscale shopping malls alongside crowded informal settlements. Policy focus on decentralization, deregulation, economic retrenchment, and the privatization of public services has intensified economic hardship. Faced with weak or ineffective state and local governments, the absence of social safety nets, and few opportunities for secure employment, more and more urban residents turn to informal activities for their living. Their economic ventures connect with the overall economy in complicated ways, crisscrossing public and private space. This is why it may make constructive sense to approach informality as an organizing logic rather than as a specific sector of the economy (Roy, 2005). In this view, informality also plays out as practice in the growth of networks and associations in the organization of urban life (Lindell, 2010). In the recent global economic recession, especially since 2008, such processes are likely to become adversely affected and constrained, hampering the ability of informal actors to break through their economic marginalization in social and legal terms.

Beyond the Informal Sector?

Regardless of the difficulties involved in defining and assessing its scope, informality has returned not only on the scholarly development agenda but also as a topic with popular appeal from two different but equally sensationalist angles: a relentless involution of economic activity and housing comprising an urban nightmare bent on self-destruction (Davis, 2005), and a self-reliant, innovative entrepreneurship employing half of the world's population (Neuwirth, 2005, 2011). Whether one is championing its creative livelihood potential or advocating its banning, there is no doubt that an informal economic culture has taken complicated roots and that its operational practices have become pervasive across the globe. Today, the most relevant questions to explore about informalizations concern the effects of political and economic liberalizations, on members of the many households whose livelihoods continue to be made from informal activity.

While the term 'informal sector' may remain part of our descriptive vocabulary, new scholarship is likely to continue to disentangle the complexities of informal activities that need to be understood in their own right if we are to establish policy programs to support them. The enthusiastic reception in some circles of de Soto's praise of the resourcefulness of the urban poor must be tempered by a recognition of the heterogeneity and change of informal sector activities as well as of the exploitative conditions under which much of this sector's work is carried out, particularly, by women and children. Lessening this state of affairs on a global scale requires more than self-help by small-scale entrepreneurs, assistance from participatory networks and organizations, and intermittent intervention by local and transnational NGOs. In effect, it also invites governmental action on many fronts to reshape the institutional structures that continue to reproduce livelihoods in the interstices of the economy.

Abstract

This article provides a selective survey of the large literature on informal work in developing countries. The literature spans a wide range of issues, including definition, measurement, impact on workers and aggregate productivity, as well as policy linkages. We highlight three sets of issues where a renewal in research seems particularly warranted: informal work and aggregate productivity, minimum wages and informal labor market outcomes, and the labor market impact of trade liberalization in the presence of an informal sector.

How important is informal work in developing country labor markets? What are some well-established facts concerning its scale, persistence, implications on policies? What are some areas of research that warrant further scrutiny? These are the objectives of this brief survey.

As preface, it should be noted that many excellent and up-to-date surveys on informal sector activity already exist, with various emphases covering definitional issues, measurement concerns, time trends, linkages with input markets other than labor, and linkages with other ongoing macroeconomic processes and/or policies. For example, Chen (2012) classifies the many types of jobs in the informal sector, summarizes the various definitions of the informal sector, and examines the important role the informal sector plays in a developing country. Schneider (2014) articulates the various measurement issues in informal sector research and argues in favor of the use of a multiple indicators multiple causes (MIMIC) estimation method due to its flexibility. In terms of overall trends, OECD (2009a,b) provide extensive overviews of the trends in informal employment around the world. Batini et al. (2010) survey the literature on informal labor and informal credit markets and argue for the need to use a dynamic general equilibrium approach to simultaneously capture both sets of issues. A recent joint International Labour Organization (ILO) and World Trade Organization (WTO) study (ILO–WTO, 2009) takes a comprehensive look at the link between globalization (trade reforms, foreign direct investment, and economic growth) on the expansion and contraction of informal jobs in developing countries.

In this survey, our focus will be on informal work in the developing world. It is thus less ambitious in scope than studies that attempt to define, measure, and assess the full gamut of informal sector activities, their determinants, and their consequences. Yet, the definition of 'informal work' itself can be challenging – what are the various types of work that come under the umbrella term informal work, and what difference does a change in definition alone make when it comes to the causes and consequences of informal work? In what follows, we begin with a broad stroke summary of the various definitions of informal work in developing countries and highlight some of the aspects of informal work that have received particular attention in the academic literature.

Our narrower focus relative to existing surveys also allows us to zone in on a few selective sets of controversies about informal work about which we believe the verdict is very much still out, and are thus potentially fruitful areas for future theoretical and empirical research. In each case, we introduce one or more features of developing country labor markets that can potentially modify/overturn standard predictions and results. We do this for three areas of inquiry. The first concerns the relationship between the productivity of informal relative to formal work. To this active area of research we introduce three oft overlooked issues, unobserved heterogeneity, imperfect competition in the labor market, and the different shades of informality that in fact exist in what is commonly referred to as the formal sector.

Next, we will revisit a large and growing literature on the impact of minimum wage legislation on wages and employment, both formal and informal. To this literature, we will introduce the role of imperfect enforcement by government enforcement agencies, imperfect commitment by policy makers, and imperfect competition in the labor market.

Finally, we examine the issue of welfare implication of trade liberalization in the presence of an informal sector. Here, we argue that research on both the theoretical and empirical fronts is nascent, and that there are a number of fruitful areas that warrant future research. In the rest of this survey, the terms work, jobs, and employment will appear interchangeably. All three terms are synonymous with paid work in informal sector enterprises including self-employment in the developing world.

Informal Work: Definition, Measurement, and Macroeconomic Correlates

According to Chen (2012), informal employment can be divided into two broad categories: self-employment and wage employment. Each of these two broad categories can be further divided into subcategories according to an individual's status in employment. For instance, informal self-employment includes (1) employers in informal enterprises; (2) own-account workers in informal enterprises; (3) contributing family workers (in informal and formal enterprises); and (4) members of informal producers' cooperatives. Correspondingly, informal wage employment includes employees hired without social protection contributions by formal or informal enterprises or as paid domestic workers by households. Chen (2012) associates informal jobs as those consisting of (1) employees of informal

 http://dx.doi.org/10.1016/B978-0-08-097086-8.94028-5

enterprises; (2) casual or day laborers; (3) temporary or part-time workers; (4) paid domestic workers; (5) contract workers; (6) unregistered or undeclared workers; and (7) industrial outworkers (also called homeworkers). These informal jobs can be also viewed as a hierarchical pyramid with unpaid family workers at the bottom rung followed by industrial outworkers and homeworkers. These two bottom layers of the pyramid are predominantly women workers. The next two (middle) layers of the pyramid are respectively casual wage workers and own-account operators with both men and women populating these two types of jobs. Finally, regular wage workers and employers, both predominantly men, constitute the two topmost layers of the pyramid. Corresponding to this job pyramid, the pay is the lowest and the risk of poverty is the highest at the bottom layers (family workers and home-based industrial outworkers) with the pay rising (and corresponding risk of poverty falling) as one moves to the top of the pyramid where employers and regular informal wage workers reside.

Estimates of informal employment based on four selected categories of (1) enterprises with less than five workers; (2) own-account workers; (3) contributing family workers; and (4) domestic workers are provided in the ILO–WTO study (2009) for a selected group of Latin American countries. Data from 2006 show that the share of each of these informal employment categories in total informal activity ranges between 22.1 and 41.5% for enterprises with less than five workers; between 38.1 and 56% for own-account workers; between 2.4 and 16.9 for contributing family workers; and between 3.9 and 18.5% for domestic workers.

Alternatively, OECD (2002) presents a system of accounts adopted by the United Nations in 1993. In this definition, informal (or underground) work is defined as work that produces all market-based goods and services that are

> deliberately concealed from public authorities for any of the following reasons: (i) to avoid payment of income, value added or other taxes, (ii) to avoid payment of social security contributions; (iii) to avoid having to meet certain legal labor market standards, such as minimum wages, maximum working hours, safety standards, and (iv) to avoid complying with certain administrative procedures, such as completing statistical questionnaires or other administrative forms.
>
> OECD, 2002, pp. 139

Studies by the OECD (2009a,b) and reported by Schneider (2014) give general estimates of informal work across the developing world that are in line with this alternative definition. These studies first estimate the incidence of informal employment in the nonagricultural sectors of the developing world between 1990 and 2007 at 900 million workers. Inclusion of the agricultural sector more than doubles this number to 2 billion workers. The OECD studies further conclude that 1.8 billion people work in informal jobs, compared to 1.2 billion who benefit from formal contracts and social security protection. Specifically, informal economic activity in the nonagricultural sector of developing countries accounts for 75% of all jobs in sub-Saharan Africa; more than 66% in South and Southeast Asia; about 50% in Latin America, the Middle East, and North Africa; and nearly 25% in transition countries. If agriculture is included, the informal share of the economy in the above mentioned regions is even higher.

Depending on how informal jobs are defined, and the number of countries in a region included, data on the time trend of informal employment across global regions vary from study to study. For instance, the OECD (2009a,b) studies show that the share of informal employment (as percent of total nonagricultural employment) has increased over time globally with the informal employment share of South- and Central American countries rising from 32.4% during 1985–89 to 50.1% over 2000–07. Similarly, the share of informal employment in Asian countries rose from 55.9% during 1985–89 to 70.2% between 2000 and 2007, while for African countries the share of informal employment rose from 40.3% during 1985–89 to 60.5% between 2000 and 2007. By contrast, ILO–WTO (2009) finds that informal employment (as a share of total employment, not total nonagricultural employment as in OECD (2009a,b)) has remained relatively stable for Latin America from the early 1990s till the 2000s at 50–52%, the corresponding numbers for sub-Saharan Africa show a decline from 63.6% in the late-1990s to around 55.7% in the 2000s. Asia, however, shows an interesting pattern with 78% of the workforce in informal employment both in the early 1990s and in the 2000s, but a drop in the late-1990s to 68.5%. These trends are interesting since the period under study between early 1990s and mid-2000s also coincide with significant trade liberalization in the developing world.

Based on these and other related estimates, researchers have attempted to ascertain the relationship between the size of the informal sector and the stage of a country's economic development, measured, for example, by the per capita GDP. To wit, the aforementioned ILO–WTO (2009) study shows that the average rate of informal employment (informal employment as a share of total employment averaged over all countries in the relevant country grouping) declines from 70% in low-income countries to 63.8% in intermediate-income countries and to 46.1% in high-income countries. This negative relationship is further borne out by La Porta and Shleifer (2014) who groups 185 countries by per capita income quartiles. Using percentage of the labor force in self-employment as a proxy measure of informality they find that the bottom income-quartile countries have 46.4% of their population as self-employed, the second income-quartile has 35.7%, the third income-quartile has 23.1%, and the top income-quartile countries have only 13.3% of self-employed people in the economy. Furthermore, La Porta and Shleifer (2014) estimate that doubling of the GDP for a country is associated with almost a 5% point reduction in self-employment. There is, however, a caveat. If economic growth is accompanied by a faster growth in the labor force then the decline in self-employment will be much slower. Thus, the transition to formality is driven by economic growth as long as the labor force does not grow too fast.

As opposed to viewing informality as an outcome determined by the stage of development of an economy, a number of studies consider informality as a potential contributor to economic growth (e.g., growth in per capita GDP). To this end, Loayza (1996) shows that for Latin American countries there exists a negative relationship between the size of the informal sector and real GDP growth. Loayza (1996) attributes the differential productivity of informal and formal sector workers as a potential reason for this result. Perry et al. (2007) argue that a large informal sector can pose a challenge to a country's public

finance and impede the country's ability to deliver public goods, raise human capital, and facilitate technological change. One potential consequence is a slowdown in economic growth.

These broad stroke summaries conceal a much more nuanced diversity in the features that labor markets with formal and informal employment exhibit. In what follows, we look at three such sets, including labor productivity, response to policies such as the minimum wage, and the impact of trade liberalization on the informal sector.

Productivity of Informal Sector Firms

De Soto (1989) famously views the informal sector as a dynamic sector where much productive potential can be harnessed if government regulations and taxes can be removed and property rights secured. This is in sharp contrast to an alternative view (Farrell, 2004), which advocates the 'hidden dangers' of the informal economy, as the informal sector is seen here as unfairly competing with legal formal sector firms. Hence, policy measures that scale-down the informal sector will be rewarded with overall productivity improvements. A third view characterizes informal sector firms as different from their formal counterparts, employing a vast reservoir of lower-skilled workers, paying correspondingly lower wages, and operating in smaller establishments. La Porta and Shleifer (2014) refer to these three views respectively as the romantic view, the parasite view, and the dual economy view. This third view sees the informal sector as an employment of last resort for the poor, and increases in the formal employment opportunities will decrease informal employment over time.

What are some potential contributors to the productivity differences between the informal and formal sector workers as seen in these distinctive views of the informal sector? We argue that empirical work in this area has not fully accounted for one or more of following issues: unobserved heterogeneity; the possibility of employer market power in the formal and/or the informal sector; and the different shades of informality that already exists within the formal sector.

To gauge the difference in labor productivity between the formal and informal sectors, two approaches are often employed. The first is a direct method which relates productivity to value added per worker (sales net of expenditures on raw materials and energy per worker). The second is an indirect method, which deduces relative productivity from data on wages received by workers in informal firms relative to workers in formal firms. (For example, based on the ratio of value-added definition, the informal productivity gap ranges from 99% (in the Democratic Republic of Congo) to 30% (in Cape Verde) with the median around 85% (in Uganda and Guatemala). Based on the relative productivity definition, on average informal wages are about one-half of small formal firms and one-third of large formal firms (La Porta and Shleifer, 2014, 2008).)

The reliability of the first approach – using the ratio of observed formal and informal value-added – depends critically on available information on the other inputs employed in formal and informal firms. These tend to vary significantly across countries and across inputs. For example, La Porta and Shleifer (2008, 2014) do not find any perceptible differences in the education level of formal and informal sector workers, instead, a huge difference in managerial human capital is found – 76% of managers in formal firms have a college degree compared to only 7% of managers in the informal sector. Other studies, however, find that although skill (or education) levels in the formal and informal sectors overlap, the average skill (or education) level is higher in the formal sector (Maloney, 1999, 2004; Thomas, 1992; Gong and Van Soest, 2002; Gong et al., 2004; ILO–WTO, 2009.). Furthermore, depending on data source, critical data on inputs are oftentimes missing. The World Bank Enterprise Surveys, for example, have data on the use of electricity generators by formal and informal firms, but not the actual physical capital input employed by the firms. In addition, the composition of inputs – whether they are from formal or informal sources – is not often clearly specified.

Specifically, many formal firms hiring a certain percentage of the formal workforce do not have regular contracts that pay social security and other worker benefits. Such a mix of long-term regular and short-term contract workers (through labor contractors, for example) has been observed in Argentina and other Latin American countries (Bosch and Maloney, 2006; Perry et al., 2007); in horticultural firms in South Africa (Barrientos and Kritzinger, 2004); in the garment industry in Jordan; and the fruit industry in Chile (Barrientos, 2008). Some motives that are often associated with the hiring of temporary workers include (1) cost savings; (2) flexibility in the presence of output demand shocks; (3) specialty skills that are not available on regular basis; and (4) the need to screen workers' ability. Empirical result in this area is nascent and includes only developed country studies (Beckmann and Kuhn, 2009). Soundararajan (2014a) is the only exception and finds using data from Indian manufacturing firms that (1) contract worker is a critically important source of labor input for Indian formal manufacturing firms, and (2) the productivity impact of the contract worker intensity is highly nuanced and nonlinear.

The reliability of the second approach – using the ratio of observed formal to informal wages – depends critically on whether the wage-determination mechanisms in the two sectors are comparable. There is a fair amount of evidence of a formal–informal sector wage gap in developing countries. For instance, Bargain and Kwenda (2010) demonstrate the existence of an informal wage penalty using evidence from Brazil, Mexico, and South Africa. Charlot et al. (2011) present evidence from Brazil indicating a wage premium in the formal sector after controlling for individual characteristics. In particular, if labor markets in the formal and informal sectors are perfectly competitive, then observed wages can be expected to be a good proxy for labor productivity. This is of course a strong assumption. To this end, Basu et al. (forthcoming) highlight two features of informal economy – the imperfect enforceability of contracts and the competitiveness of the labor market – and show that the two are in fact incompatible with one another in a model of the formal and informal sectors with search frictions and self-enforcing contracts. The model is consistent with a host of salient observed features of informal labor markets, including wage dualism, and nonmonotonic unemployment response to a minimum wage hike. Thus, without further information about the deviation from marginal productivity pricing, wage differences are in general a poor proxy for formal and informal sector productivity differences.

Minimum Wage Legislations and Informal Work

Standard models of the informal labor market typically aruge that an artificially high minimum wage in the formal sector gives rise to informal sector employment. Within this general framework, there are two classes of models each with different views on the determinant of informal sector employment. Dual' labor market models following Fields (1975) view the informal sector as a by-product of urban unemployment that arises as a result of rural–urban migration generated by the downward rigidity of a legislated minimum wage in the urban sector. This class of models does not view informal enterprises as deliberately avoiding regulations but rather as employers of last resort for otherwise unemployed workers. On the other hand, the 'voluntarist' school views informal sector firms as deliberately avoiding labor market regulations like the minimum wage, social security contributions, and worker benefits that increase labor hiring costs for employers. Some employers, especially in countries with low-enforcement intensities, circumvent these legislations by choosing to operate in the shadow/informal economy (Johnson et al. (1997) and Johnson et al. (1998) as examples).

These models tend to generate very different predictions concerning the impact of a minimum wage hike on (1) subminimum wages, (2) informal sector employment, and (3) unemployment. For some time, these predictions have met with mixed confirmation in the empirical literature, where a number of salient features of informal labor markets have begun to take root. Basu et al. (forthcoming) highlight four such features:

- There is widespread noncompliance to minimum wage legislation both in the formal and informal sectors.
- There is coexistence of compliant and noncompliant employers.
- There are broad ranges of noncompliance, where a spike at the official minimum, typically occur alongside a dispersion of subminimum wages in covered sectors.
- Observed unemployment response to the minimum age is mixed ranging from positive, to insignificantly different from zero, to negative.

These observations challenge both the theoretical and empirical literature on informal work in a number of important ways. First, in terms of theory, these observations call for a unified theoretical model that is capable of reconciling these diverse empirical findings. Basu et al. (forthcoming) take a first stab and write a model combining an imperfectly competitive labor market, an imperfectly enforced minimum wage, and imperfect commitment to the minimum wage policy by policy makers. In doing so, the paper questions why authorities turn a blind eye to the very legislation that they have themselves passed. The model generates an inverted-U relationship between changes in the minimum wage and employment. It explains the selection into compliant and noncompliant firms among a continuum of heterogeneous firms in terms of productivity. The model also explains the spike at the minimum wage as the marginal cost of labor exhibits a discrete jump at the legislated minimum wage. Finally, the model explains how in the presence of imperfect enforcement, employment response to a minimum wage hike can remain the same as the setting with perfect enforcement, exhibit a muted response, or exhibit the opposite sign.

Soundararajan (2014b) presents the first empirical study to formally test the above results. Using a repeated cross-sectional data set from the nationally representative employment surveys of India for the years 2004–12, the study estimates the interactive effect of minimum wages and enforcement on employment, wages, and days of work in the construction industry – the second largest industry in India after agriculture. The study finds an inverted-U relationship between minimum wage and employment after controlling for imperfect enforcement of the minimum wage.

Many interesting areas for future research in the area remain. For example, labor market regulations are not the only regulations faced by firms that operate in the formal sector of developing countries. Indeed, in addition to minimum wages, formal firms are often obliged to pay government authorities a tax on profits earned and withhold taxes on wage income to be transferred directly to authorities. By comparison, informal firms and informal workers are free from both the state-mandated regulation on wages, the need to pay taxes on profits or wages, and operate in an environment where entry and exit may be seen as more or less cost-free. In the presence of multiple regulations imperfectly enforced by different agencies (tax auditors and labor inspectors), Basu et al. (2012) set out to answer a number of additional questions: (1) how do profit tax, personal tax, and the intensity of tax enforcement impact tax evasion and minimum wage noncompliance? (2) How do a minimum wage hike and stricter enforcement of the minimum wage impact the extent of either of the profit or personal tax evasion or exit by formal firms? It is shown that tax evasion is increasing with the profit tax rate and the minimum wage, and decreasing in the personal income tax rate. Meanwhile, noncompliance with minimum wage on the other hand is independent of the profit tax rate and increasing in the personal income tax rate. The next set of open issues is accordingly an empirical investigation into the role of multiple policies (e.g., minimum wage and taxes) on the multiple types of informal activities (e.g., tax evasion, informal employment).

Trade Liberalization and the Informal Sector

The national welfare implication of trade liberalization is a subject of longstanding importance in the economics literature. Importantly, in a whole range of possible settings including neoclassical trade models featuring perfect competition in input and output markets (Chau and Färe, 2011), or the latest class of models incorporating heterogeneous firms (Melitz, 2003), trade liberalization is expected to bring unambiguous welfare gains. The former operates through more efficient allocation or resources as trade barriers are removed, while the latter operates through the exit of lower productivity firms as trade liberalization promotes competition between domestic and foreign firms.

None of these settings, however, incorporate possible complications when the informal sector is included in the analysis. Despite the importance of the informal sector in developing countries, to date there are in fact only a handful of empirical and theoretical studies on the subject. Already, however, what we have learned suggest that the welfare implications of trade liberalization are highly nuanced as soon as considerations are given to the informal sector.

Consider, therefore, two popular indicators of trade liberalization – trade openness (sum of exports and imports) as a share of GDP and average foreign direct investment liabilities. ILO–WTO (2009) demonstrates that among five Asian countries (China, India, Indonesia, Thailand, and Sri Lanka), informal employment in countries with low-, intermediate-, and high-trade openness are 80%, 74.6%, and 72.4%, respectively. This negative relationship is preserved with a larger set of countries and also when openness is measured based on average foreign direct investment liabilities. The reasons for these differences are often seen to stem from the exit of least-productive informal firms as a consequence of trade liberalization, particularly when a productivity gap between formal and informal sector firms prevails (La Porta and Shleifer, 2008; Hsieh and Klenow, 2009; McCaig and Pavcnik, 2013). Fugazza and Fiess (2010) likewise produce mixed findings and show that the results depend in particular on whether the empirical analysis employs cross-country or cross-firm evidence. Complementing these findings relating informal sector employment with trade liberalization, Soares (2004) provides evidence on the impact of trade reforms on wages in the informal sector in Brazil between the 1980s and 1990s. The results suggest a reduction in the wage gap between formal and informal sector workers driven by a fall in the very high wages enjoyed by formal sector workers prereform. By contrast, Bargain and Kwenda (2011) find a wage penalty for lower-tier informal sector workers vis-à-vis the formal sector counterparts in Brazil over 2002–07 time period and South Africa over the 2005–08 time period.

These and other related empirical evidence to date notwithstanding, there continues to be very little theoretical developments in the area to organize these results. An exception is Becker (2014), who proposes a trade model with heterogeneous firms incorporating the informal sector, wage dispersion due to productivity heterogeneity, and a concern for fair wages on the part of workers (Akerlof and Yellen, 1990). The model is uniquely suited to analyze firm exits out of and entry into exporting, the formal sector and the informal sector subsequent to trade liberalization. The model produces findings consistent with Nataraj (2011), for example, which shows that the productivity improvement observed subsequent to the Indian trade liberalization in 1991 arise in large part due to the exit of the least-productive informal firms. Furthermore, the model also generates results on wage responses to trade liberalization.

Conclusion

Despite the many new advances summarized here in studies related to informal work in developing countries, many issues remain. For example, the informalization of formal sector work, such as through the subcontracting of formal work, is an area of research that has received very little attention due both to the paucity of data and the lack of a theoretical basis with testable hypothesis, and associated policy prescriptions. The appropriateness of a minimum wage policy depends both on the extent to which the minimum wage is enforced and the extent to which employers exhibit market power. In both of these areas, more empirical observations in a wider range of countries are needed. Finally, ongoing work on the role of trade liberalization on informality has focused almost exclusively on goods-trade liberalization, while the impact of an influx of foreign investment, and as such foreign competition for domestic labor in formal and informal sectors remains largely an open question.

Information and Communications Technology in Education

Saïd Assar, Telecom Ecole de Managment, Institut Mines-Telecom, Evry, France

Abstract

As Information and Communication Technologies (ICT) gradually permeate daily life, they are profoundly changing the way education is conceived and delivered. Teachers play a key role in this transformation process; their beliefs, pedagogical practices, and teaching skills are continuously challenged. ICT integration in the educational process can significantly enhance traditional courses and Internet-based education, i.e., e-learning, is becoming a serious alternative to traditional, face-to-face courses. To be used as a lever for pedagogical innovation and institutional transformation, teacher ICT competencies need to go beyond skills in ICT use per se, and enclose contextual knowledge about technology, pedagogy, and content. On the other hand, learners' engagement with ICT in education depends on their expectations and conceptions of learning and required assessment. A learner's experience with ICT in education is linked to his perception of systems' ease of use and usefulness in achieving learning goals. Adaptive learning systems open new potentialities for a personalized instruction which is tailored to the learner's characteristics. At the edge of a new era, schools, colleges, and higher education struggle to seize opportunities and overcome obstacles.

Introduction

Education is existential for human societies; it is a fundamental leverage for social preservation and economic growth. For centuries, the way education is performed remained the same: the teacher talks and acts, while pupils listen, watch, and write. Printing machines made textbooks widely available and knowledge rapidly spread; educational institutions appeared and developed all over the world. However, the way education was performed did not change so much and remained teacher centered. With the emergence of new technological devices for handling picture and sound, new possibilities for knowledge transmission emerged. Instead of handmade drawings, photos could be used to present study subjects, for example, in biology or physics courses. Using audio recordings, pupils learning foreign languages could, at their convenience, listen to native speakers and practice their lessons. With animated pictures and movies, a chemistry course could be illustrated with the visual transcription of a complex experiment. Television took education a step further as lectures and seminars could be broadcasted. The *Gyan Darshan* educational TV channel in India, for example, aired on a large-scale programs originating from institutions all over the country for the benefits of millions of Indian students (Rani, 2006). However, it is the rise of computers and personal computers – combined with the rapid expansion of Internet – that opened a wide area of new applications and usages in education.

Fast development in Information and Communication Technologies (ICT) is shaping a new world in which education at all levels can no longer be assimilated to a group of learners in a classroom listening and watching a teacher with a textbook following a fixed curriculum. With ICT, learning is shifting from teacher centered to learner centered and can potentially be undertaken anytime and anywhere, from classrooms to homes and offices. E-learning refers to learning via the Internet; it provides learners with a flexible and personalized way to learn (Zhang and Nunamaker, 2003). It offers learning-on-demand opportunities and can significantly contribute to reduce teaching and learning costs. E-learning is the enabler for a massive transformation in the education world; new teaching and learning opportunities are continuously challenging traditional schools, colleges, and higher education (Oliver, 2002; Collins and Halverson, 2009). However, effective and innovative use and integration of ICT in education is a complex and multifaceted problem. Complexity lies in the intertwining of technology, pedagogy, user adoption, and institutional policies (John and Sutherland, 2004). ICT encompasses many different things, and can address multitude challenges; in fact, to teach and to learn with ICT remains partially understood, and all its benefits are still not fully exploited (Cuban, 2001; Kirkwood, 2009). Furthermore, from primary schools to higher education, scientific evidence is still insufficiently available about the effectiveness of ICT integration in education (U.S. Dept. of Education, 2010).

Digital Resources for Education

There are three general and complementary categories of ICT artifacts to be used in teaching.

- The first category is stand-alone digital components to be used to support learning inside a course for didactic and/or assessment purposes. Called also Digital Learning Material (DLM) or Learning Objects (Polsani, 2006), it includes video clips (e.g., a YouTube fragment), illustrations (e.g., photos and drawings), simulations (e.g., simulation of an organizational process or an electronic circuit), and interactive assessment resources (e.g., quiz) (Kreijns et al., 2013).
- The second category includes general tools for communication and information diffusion such as Really Simple Syndication (RSS), blogs, chat and voice over IP, peer-to-peer file sharing, wikis, web conferencing, and social networks. These tools were not specifically designed for teaching; however, they can support the teaching purpose by providing communication facilities in pedagogical scenarios.

- The third category resembles software systems to run a course. Called also Learning (or Course) Management System (LMS or CMS), these complex tools are educational software packages for online course administration and delivery (Morgan, 2003). Their main functions include course content organization and presentation, students recording and tracking, class activities management, teachers and learners' communication, student assessment tools, and grade books tools. Other terms used to denote such systems are Web-Based Learning Systems (WBLS), Virtual Learning Environments (VLE) or, more simply, learning platforms. Blackboard and Moodle are common examples of learning platforms in higher education (see Web references).

Simple learning objects (e.g., a video sequence or a quiz) can be composed into more complex educational resources and made available on their own in the form of a CD-ROM or interactively online. They can also be part of complex software applications dedicated to providing learners with specific assistance while learning a particular subject, e.g., mathematics (cf *see* Computer Assisted Instruction). For primary and secondary school, simple and composite learning objects are a common way to integrate ICT in teaching. In higher education, this approach is particularly common as well: learning objects are integrated in face-to-face lectures; they can also be part of courses provided online through a learning platform. Learning platforms can be used either for blended learning where face-to-face teaching alternates with and complements online teaching, or for fully online learning where no face-to-face interaction occurs (i.e., virtual learning). In both cases, different communication and information diffusion tools (e.g., blog, wiki) can be used in combination with the learning platform.

Teachers and ICT

Teachers are critical change agents at the academic work floor; they are the instrument by which changes in education will become true. In an extensive literature review, Mumtaz (2000) summarized what influence teachers' attitude toward technology use in school: available and easy-to-use digital resources, incentives to change and support from colleagues and school managers, clear and understandable school and national polices, and background in formal computer training. A worldwide educational survey at primary and secondary education levels confirmed these early indications. Pelgrum (2001) assessed ICT integration in teaching and ranked three factors as most significant barriers: (1) computers insufficiently available, (2) teachers' lack of ICT knowledge and skills, and (3) difficulties in integrating ICT in instruction in a relevant manner. Furthermore, teachers tend to ignore the full potential of ICT to power the learning environment. For example, in the Netherlands, a survey in the highest grade primary schools found that 60–80% of teachers in the sample never used CD-ROM encyclopedias and information search on the Web (Smeets, 2005). In another survey, in higher educational institutions, 51% of teachers considered that the quality of students' learning in their course did not improve using Internet; and 27% think that e-learning environments have no added value for their course (Mahdizadeh et al., 2008: p. 148).

Nonetheless, teachers' adoption of ICT use in teaching cannot be restricted to merely technology-related factors: "integration of educational computer use in professional competencies of teachers implies a more complex approach" (Tondeur et al., 2008: p. 2542). Beyond factors related to technology resource and education management, teachers' beliefs about teaching and learning with ICT are essential and need to be fully taken into account (Mumtaz, 2000; Cloke and Sharif, 2001). Teachers' beliefs are understandings, premises, or propositions felt to be true about the educational purpose and the educational process. They are rooted in teachers' perception of their role and mission as knowledge owners and knowledge transmitters. Established typologies distinguish between 'traditionalistic' or behaviorist, teacher-centered, and more 'progressive' or constructivist, student-centered beliefs (Tondeur et al., 2008: p. 2544). These two types are not exclusive; research in the last decades on the dimensionality of educational beliefs has acknowledged a multidimensional vision of the belief system. For example, Tondeur et al. (2008) found that most frequent adoption of all types of computer uses is amid teachers with relatively high constructivist beliefs and also high traditionalist beliefs.

To make teachers adopt a more constructivist perspective, they primarily need to gain a broader and deeper understanding of what is expected from ICT integration in class. They also need to acquire higher self-confidence through improving their ICT self-efficacy and their awareness of ICT potential. Furthermore, encouraging teachers' experimental behavior and training them with pedagogy-oriented ICT skills can be strong determinants of ICT adoption in teaching (Kreijns et al., 2013). In fact, the knowledge and skills that teachers need to acquire will differ depending on the content that is taught and the pedagogical goal. This can vary from improving learning effectiveness in school subjects to promoting the development of specific skills such as lifelong learning and learning to learn.

Pedagogical Issues

ICT alone does not improve teaching; rather it is the ways in which ICT is incorporated into the various learning activities that is of crucial importance (John and Sutherland, 2004). This will depend on the teacher and on his pedagogical approach in presenting content knowledge. Shulman (1987: p. 8) defines pedagogical content knowledge as "the blending of content and pedagogy into an understanding of how particular topics, problems, or issues are organized, represented and adapted to the diverse interests and abilities of learners, and presented for instruction." The challenge with ICT lies in exploiting its vast possibilities to incorporate adequate digital resources – created from scratch or reused from existing material – into his teaching process in order to support the pedagogical content knowledge he intends to present. Learning theories can be helpful in guiding this process to build ICT-based curriculums (Ally, 2008).

To illustrate the contribution of learning theories in shaping ICT usage, Mödritscher (2006) conducted an experiment in

which he designed a virtual course (i.e., fully online) according to three well-known theories: behaviorism, cognitivism, and constructivism (cf *see* Learning Theories and Educational Paradigms). These three courses had identical knowledge goal and content, but pedagogically, were developed differently. The first (i.e., behaviorism) was structured as three modules provided sequentially to the students, and the learning process was assessed by typical behaviorist elements like multiple-choice questions. The second (i.e., cognitivism) course was organized in two phases: first, three groups of four students each worked on the course's objectives; second, the groups (dispatched differently) had to restructure the result of the first phase and synthesize the content in a wiki environment. Assessment was done by grading the result of each phase based on quality and quantity. The third course (i.e., constructivism) was organized in such a manner to lead students to build the knowledge content collectively. The four groups were given all material, and the task was to create a document for mediating the course's learning objectives to colleagues. The three members of each group had then to compare the works of the other groups and evaluate them. Results showed that each of the three courses varied in various aspects such as learners' and teacher's effort and effectiveness. The behaviorist and constructivist approaches showed better results in teaching effectiveness and earned better rating from students. Furthermore, the best efficiency in knowledge transfer was obtained through those tasks that students had to complete on their own (Mödritscher, 2006).

Beyond pedagogical approaches to ICT integration in teaching, there is a serious issue that arises: is it teaching 'with ICT' or teaching 'about ICT?' When teaching, for example, a basic statistical technique using a spreadsheet (e.g., Excel), there is always a risk that the focus is on the tool and not on the subject. According to Selinger (2001), we need to teach ICT skills in ways that "enable students to perceive the benefits and potential of using computers to support their work" (p. 144). Because it is difficult to teach ICT tools without their usage contexts, both should be taught simultaneously: the content material with the help of ICT (e.g., accounting), and effective ICT skills (e.g., how to use Excel). However, among teachers, ICT integration in teaching practices is still difficult to understand. For example, in a survey among primary school teachers in Tondeur et al. (2007) found that, although the governmental ICT curriculum centers on the integrated use of ICT within the learning and teaching process, "teachers in primary education still stress to a large extent technical ICT skills" (p. 972). Teachers need to better understand how ICT can be integrated in teaching, and what kind of skills they require (cf *see* Teacher Education).

A Framework for Teacher Knowledge

The Technology, Pedagogy, and Content Knowledge (TPACK) framework is a proposal to develop teacher knowledge in the ICT-based education era (Harris et al., 2009). It is intended to help teachers successfully integrate technology into their teaching practice. It is based on a recurring observation: "different disciplines have differing organizational frameworks, established practices, ways of acknowledging evidence and proof, and approaches for developing knowledge" (Harris et al., 2009: p. 395). It claims that it is insufficient to expose teachers to particular technological tools and resources and their possible curriculum-based educational use. There are complex relationships among content, pedagogy, technology, and context that teachers need to understand and conceptualize in order to put these technological resources into practice. The TPACK framework emphasizes "the connections among technologies, curriculum content, and specific pedagogical approaches"; it is expected to demonstrate "how teachers' understandings of technology, pedagogy, and content can interact with one another to produce effective discipline-based teaching with educational technologies" (Harris et al., 2009: p. 396).

Activity types are the building concept in the TPACK framework. An activity type is a content-oriented teaching pattern which conceptualize notions of pedagogical content knowledge mentioned before (Shulman, 1986, 1987). It acknowledges the need for particular pedagogical techniques when teaching a particular content. It is a structured representation of pedagogical techniques that can be associated with classroom activities, interactions, and recognizable material for a particular content. For example, one of the first proposals of such teaching pattern mentioned in educational literature is the Mehan (1979) I–R–E sequence: teacher Initiation, student Reply, teacher Evaluation (cited in Harris et al., 2009: p. 404). Other well-known pedagogical techniques, such as 'to have a discussion,' 'to brainstorm an issue' or 'to make an experiment,' can be further refined in order to form activity types. However, because of the interdependency between pedagogy and content, an activity type has to be defined in the context of a specific teaching domain. 'To make an experiment,' for example, would be defined differently depending on the content: in a chemistry course, it would mean going to the laboratory and manipulating material and measurement tools; in a foreign language course, it would mean composing linguistic constructs and evaluating them.

Concretely, for a given content, the TPACK framework gradually and incrementally matches relevant activity types with adequate technological resources (see Web references). For example, in the mathematics domain, a typical interpretation activity type is to 'develop an argument.' Candidate technologies to support this activity would be concept mapping software, presentation software, and specialized word processing tools (Grandgenett et al., 2011: p. 3). Another possible activity in teaching mathematics is to 'describe an object or concept mathematically'; candidate technologies would be specialized tools such as Logo graphics, engineering visualization software, or Mathematica software package (Grandgenett et al., 2011: p. 4).

Learners and ICT

Learner acceptance is a key issue when using ICT in education. It will depend on two sets of intertwined factors: the first concerns ICT's role in the educational process and how it contributes – directly or indirectly – to better performance, the second relates to the learner's own experience while using ICT for educational purposes. For example, when instructors make

available to students recorded lectures as audio and video podcasts to download, learners' attitudes and opinions will depend primarily on the extent to which this facility can contribute to successful grading in the course. In turn, this will depend on podcasts' content, and how it complements – or supplements – face-to-face lectures. Beyond traditional lectures, availability as podcasts of short revision summaries were, for example, highly appreciated by students (Copley, 2007). On the other hand, learners' attitudes will also depend on their experience in downloading, storing, and using the audio and video digital files. File size, file format, text size, and video resolution then play a key role; in addition, the ease of use and flexibility of podcasts will contribute to learner satisfaction.

Let's illustrate how multiple factors intertwine in shaping learners' perception according to educational contexts and scenarios. Kay and Knaack (2008) report a large survey to better understand how teachers and students perceive learning objects in secondary schools. Although students were less positive than teachers, they rated positively visual support, ease of use, and animation with learning objects; they also felt better engaged with the course. Negative remarks mentioned inadequate level of details in certain graphics and the use of different wording and explanation methods than those used in class. Kirkwood (2008) investigated how undergraduate learners use online resources. He finds that most learners use the internet for "personal, domestic, social and employment purposes as well as for educational goals" (p. 381), but seeking information resources is most frequent when it is directly useful for their ongoing studies, particularly in relation with assessment. He insists however on the importance of adequate ICT literacy in terms of copyright and plagiarism issues, identifiers and passwords management, and protection against malicious software.

Nonetheless, it is the student's perception of distance education through the Internet (i.e., e-learning) that received highest attention. Researchers regularly investigate the extent to which e-learning is appropriate for all students and is an effective manner to provide education. In 2004, Allen et al. analyzed previous empirical studies; results showed that distance learning slightly outperformed face-to-face classes on the basis of performance (i.e., ability to master content and skills). The highest improvement was for teaching specific contents, e.g., foreign languages (Allen et al., 2004: p. 413). Concannon et al. (2005) surveyed students in an undergraduate blended course – lectures and laboratory sessions were supplemented with online course content. They found that e-learning adoption depended on the learner's general attitude and skills with computers, awareness of online resources availability, peer influence, and instructor support. Complaints concerned difficulties in navigating through the resources and technical problems in accessing the platform. Hence, authors issue some tips to ease students' use of learning platforms: email notification when new material is online (students often did not notice that new material was published on the platform), high-quality tutorials on how to use the system, and feedback on students' questions along with comments. Globally, although students "experienced a real improvement in the quality of their education experience" (p. 511) and considered ICT as a valuable support to the learning process, 81% of them claimed "traditional lectures and tutorial groups result in more effective student learning than a pure e-learning environment" (p. 508). A more fine-grained study of students' perception of e-learning showed that students favored face-to-face learning over online learning when confronted with acquisition of certain specific knowledge and skills, e.g., "conceptual knowledge in the subject matter, skills in the practical application of one's knowledge, knowledge and skills in using scientific work routines, or in communication" (Paechter and Maier, 2010: p. 296). Another recent study found comparable results when analyzing students' attendance (Larkin, 2010): "contrary to popular belief, Generation Y students in general, do not aspire to replace lectures with downloadable, online versions" in fact, they "valued the opportunity for interactive learning provided by face to face teaching" (Larkin, 2010: p. 238).

Indeed, the actual tendency is to align learner's adoption models with general models of technology adoption, i.e., Technology Adoption Model (TAM) (Lee et al., 2003). Hence, perceived system quality, e.g., platform ease of use and learner's interface user-friendliness, is the first global factor that directly impacts learners' adoption (Chang and Tung, 2008; Shee and Wang, 2008). The second factor measures the global usefulness of technology-based educational process for attaining learners' goals. Paechter et al. (2010) found "achievement goals proved to be more important than other course characteristics, e.g., the design of the learning material or the user friendliness of the learning platform" (p. 227). Thus, they suggest that instructors should increase learners' motivation by adapting instruction accordingly, e.g., clarifying learning objectives, providing self-tests to assess progress all along the course.

To conclude this section, it is worthwhile to mention adaptation and personalization techniques. As learning is a complex and sophisticated process in which individual traits and characteristics can interfere, adaptive learning systems seek to adjust the content, the appearance, or the process to learner's knowledge level, goals, and other characteristics (Papanikolaou et al., 2002). The aspiration is to break the 'one size fits all' educational paradigm and to provide personalized content, to protect learner from cognitive overload and disorientation, and to better assist learner through the learning process. The basic ideas behind such approaches is to classify learner according to a certain user model, and then match learner profile with adequate content, representation, or process (De Bra et al., 2009). A basic and widely known user model is prior knowledge: students are classified into groups that have similar ability and knowledge. Adaptation (i.e., automatic personalization) in such case is relatively straightforward: a quiz or a test determines learner level, and accordingly, directs learner to specific learning material. However, most of the existing research on adaptive learning is devoted to model learner according to his learning preferences, i.e., learning style. Learning style is the person's preferred way to learn and the way he/she learns best. More complex definitions include cognitive characteristics, in addition to affective and psychological behaviors (cf *see* Cognitive Styles and Learning Styles). Adequately tailoring learning material to student learner style is a complex and open problem, and actual results seem – for the moment – contradictory and controversial (Brown et al., 2009).

However, it is widely acknowledged that personalization and adaptability in technology-enhanced learning will have enormous potential for improving the user experience.

Conclusion

ICT is no doubt profoundly transforming education. In order to fully benefit from this ongoing revolution, academics need to reassess their own beliefs and pedagogical practices concerning teaching and assessment and their potential impact on learners' experiences. Both teachers and learners need to understand how ICT should be integrated in education, why e-learning activities are to be undertaken, and what expected rewards can be derived. ICT literacy for education, i.e., necessary ICT skills and knowledge for educational purposes, at individual and organizational levels, is the foundation for modern societies to reinvent teaching and learning in the age of technology.

Abstract

Information is data that have meaning. In organizational contexts, meaning derives from sense-making frameworks that reflect organizations' properties, including communication within and between organizations. Organizations transmit different messages internally than externally.

Knowledge is an accumulation of information. Whereas information changes rapidly, knowledge changes incrementally. Distinctions between data, information, and knowledge are often ambiguous, as sense making depends on knowledge, which derives from information.

Information and knowledge have grown very important in developed economies. Some developing countries have been investing in advanced education, so they have been replacing developed countries as suppliers of expertise.

Explicit efforts to manage knowledge yielded some successes and many disappointments.

Properties of Information and Sense Making by Organizations

Information is data that have meaning. Meaning arises as organizational sense-making frameworks interpret data. This sense making depends on what people already know as well as what data people can access.

Organizational information derives its meaning from the sense-making frameworks that characterize specific organizations. Many organizational members need information in order to fulfill their responsibilities, so other members gather data and convert it into information. Organizations can acquire data by scanning environmental data sources, by ingesting new members, or through internal activities such as accounting and research. Many organizations may have explicit strategies to acquire information and to maintain and archive information and knowledge. Most organizations include personnel who specialize in data acquisition or information processing, and large organizations have departments that focus on such specialties. Organizations convert data into information by discussing the implications of data, by adding to databases, or by feeding data into decision processes. They process information by filtering it, integrating it, disseminating it internally, and interpreting its implications. Nearly all organizations incorporate rules and procedures that cause personnel to initiate actions or to halt actions when they receive information that satisfies certain conditions.

Strangely, both managers and scholars paid little attention to the centrality of information in organizations' activities until the last half of the twentieth century. Not until the 1950s did articles and books begin to portray managers and work groups as decision makers. In 1958, March and Simon pointed out that information sources and channels affect organizations' perceptions, intraorganizational conflict, and goal coherence. They emphasized the human limitations that prevent people and organizations from acquiring and processing unlimited amounts of information. They also characterized people and organizations as using programs to process information, an analogy to computers.

Weick (1969) offered the first comprehensive analysis of organizations as information-processing systems. Weick treated information processing as the essence of organized activity. Indeed, he argued that organizations are not static systems and that organizing is a never-ending process through which organizations continuously evolve. This evolution occurs primarily in ideas, perceptions, data, beliefs, and communications, and people are endlessly choosing whether to follow standardized routines. Whereas Weick described evolution within one organization, Nelson and Winter (1982) described processes of imitation and knowledge transmission that foster evolution by populations of business firms. Evolutionary ideas have subsequently guided studies of technological development and the diffusion of knowledge.

Hodgkinson and Sparrow (2002) reviewed multitude psychological studies and sought to identify the key elements of 'strategic competence,' the ability of an organization to learn what it needs to learn and to remember what it ought to remember. They emphasized that humans have limited capacities for information processing, so they rely on simplified schemas to navigate complex, data-rich environments. These schemas incorporate biases and filters that can both facilitate action and foster errors.

Beginning late in the twentieth century, many organizations turned away from meetings in which managers pool their judgments and develop perceptions collectively, and instead, these organizations are educating managers about actual properties of organizations and market environments. This trend has propelled the SAS Institute to more than three decades of double-digit growth. The institute's product integrates an Executive Information System with data warehousing, data analysis, client-server computing, applications development, graphics, report writing, project management, and decision support (Taylor, 1996).

The trend toward more objectivity and less subjectivity has involved data gathering. Data warehouses are massive databases that describe past transactions. Plummeting costs of data storage allow organizations to simply record everything, without having to decide in advance what information to

 http://dx.doi.org/10.1016/B978-0-08-097086-8.73074-1

gather and retain, so earlier decisions about what to record do not limit later analyses. For example, a data-warehouse analysis enabled a large cosmetics company to avoid making a costly pricing blunder. This company buys data recorded by checkout scanners in chain stores, and it gets daily reports from sales personnel who record data from retail outlets and transmit them to headquarters nightly. When a major competitor introduced a new product, this cosmetics firm planned to make a defensive price reduction on its own high-priced product to keep the new competitor from taking too much business away from that product. However, analyses of scanner data revealed that the new product was not actually competing with the company's high-priced product; it was competing with a product that had a much lower price.

On the other hand, organizations may gather data or process information so poorly that they damage performance. For example, a rapidly growing health-care insurance firm processed receipts from clients much faster than it did claims from doctors and hospitals. As one result, this firm greatly overestimated its revenues, underestimated its costs, and made unrealistic forecasts about its profits … until the manager in charge of information processing reported that bill payments had fallen in arrears by nearly a year.

Cohen and Levinthal (1990) proposed that organizations differ in absorptive capacity, which they defined as an ability to see the potential value of new information, to assimilate it, and to apply it. They pointed to ways in which research and development activities enhance absorptive capacity.

Organizations acquire some of their sense-making frameworks from commercial markets. Publishers release many books every year that promise to provide better ways to analyze situations and better solutions for problematic situations. Organizations hire consultants who claim that they can improve organizations' performance by analyzing economic environments, potential customers, competitors, employees' capabilities, unexploited resources, and so forth. Gurus assert that their distinctive insights can transform mediocre performance into superb performance. However, the chances are remote of coming up with a genuinely effective new idea, and several studies have found that claims about the effectiveness of new sense-making frameworks have had weak support. Organizations have adopted new jargon but either have not attempted to make changes or have obtained poor results from changes they made.

Probably because ineffectiveness saps demand, the markets for sense-making frameworks have been quite faddish (Calhoun et al., 2011). Yet, there have been long-run trends arising from workers' higher educational levels, increasing availability of data, increasing technological complexity, and globalization.

Communication within Organizations and between Them

Communications in organizations reflect the statuses and aspirations of organizations' members. People in hierarchies talk upward and listen upward. They send more messages upward than downward, they pay more attention to messages from their supervisors than to messages from their subordinates, and they try harder to establish rapport with supervisors than with subordinates. People also bias their upward messages to enhance good news and to suppress bad news. However, the studies that support these patterns occurred before modern telecom technology came into widespread use. Newer technology has been flattening organizational hierarchies and facilitating lateral communication.

Formal communications in organizations are systematically troublesome. Organizations bias their formal reports to win the support of employees, customers, investors, and the public, and the members of organizations use formal reports to promote their careers or other interests. As a result, formal reports contain many misrepresentations and biases, and organizations that take formal reports seriously are prone to run into trouble (Altheide and Johnson, 1980). Such issues raise the importance of informal communication. For instance, more profitable business firms pay less attention to formal reports and rely more strongly on informal communication, and more profitable firms base their analyses on information from more diverse sources.

Organizations differ in terms of which communication modes are beneficial. Military organizations may be more effective when they restrict communication channels, whereas research institutes may benefit from open channels and random interactions. Informal communication such as work interrupted by phone calls, random chats on the way to meetings, unplanned meetings among employees, and unexpected interactions in halls can be just as important as formal communication to people's willingness to take action. Message recipients assess information quality by properties such as timeliness, richness of detail, and verifiability through two-way conversations.

Galbraith (1973) proposed an approach to organization design that focuses on the communication needed to coordinate tasks. He pointed out that behavioral programs can substitute for communication. If tasks can be adequately defined as programs and if personnel follow these programs, personnel can coordinate their actions with little communication. Programs are effective, however, only when organizations face familiar situations. If organizations continually encounter new situations, old programs become ineffective and personnel have to coordinate by communicating with each other. Galbraith pointed out that organizations can make communication less necessary by separating tasks into self-contained clusters and by lowering performance goals, thus leaving some resources underutilized. Organizations can also substitute direct horizontal communication across departmental boundaries for vertical communication up and down hierarchies; this moves decision making down to lower-level people who possess needed information rather than transporting information up to higher-level decision makers.

Innovations in communication technology have had mixed effects. Until very recently, technology has compromised informal communication by failing to support facial expressions, voice inflections, and two-way interactions. The emerging availability of video support for communication alleviates these limitations. Moreover, technology has also been promoting more informal, ad hoc, and choice-oriented communication. In global organizations, technology has been facilitating more timely coordination and bringing lower-level employees closer to higher-level managers.

Managers send quite different messages to internal audiences than to external audiences. For example, they may describe a current situation as an opportunity to internal audiences while characterizing it as threatening to external audiences. Competing organizations emit misleading information and they hide their planned actions.

Properties of Knowledge

Knowledge is an accumulation of information. Whereas information comprises a flow that changes rapidly, knowledge is a stock that changes only incrementally. Some knowledge is explicit; other knowledge is tacit. Activities such as teaching, consulting, and practicing law draw on extensive knowledge without processing large amounts of current information. Other activities such as bookkeeping and data entry process much information without using much knowledge. However, distinctions between data, information, and knowledge are often difficult to draw, as the conversion of data into information depends on knowledge that derives from data and information. Since the meaning of knowledge arises in part from its structure, knowledge reflects the intentions of the people who compile or organize it, and different people often extract different knowledge from a shared flow of information.

An organization's knowledge is both more and less than the sum of the knowledge held by its individual members. Organizations can store knowledge in routines and social norms that they transmit to new members, so organizational knowledge can include the discoveries of former members who have departed. Organizations can also purchase databases and computer programs from other organizations. Nonaka (1994) argued that organizations can only share and organize explicit knowledge, whereas individuals often acquire knowledge tacitly and their tacit knowledge must become explicit before it can become organizational. However, Cook and Yanow (1993) described a production process in which workers transmitted techniques to each other without explicit communication. Nonaka and Takeuchi (1995) described knowledge development as spiral in which employees' interactions produce repeated conversions of knowledge between its tacit and explicit forms.

Unshared knowledge can be a source of power for individual members (Starbuck, 1992). Some knowledge produces strong bonds between specific members and external constituents, and these bonds remain the property of the individuals rather than their organizations.

Scholars have debated the circumstances in which organizations should exploit current knowledge versus searching for new knowledge. However, such a choice seems to be more academic than practical, because people make unclear distinctions between use and search and they apply confusing labels to the transformations of information and knowledge. People who perform very similar tasks may describe their activities rather differently as applying old knowledge to new problems, as creating new knowledge, or as preserving knowledge (Starbuck, 1992). It can be difficult to distinguish between creating knowledge and applying it, because research may have direct applicability and efforts to apply knowledge may yield fundamentally new insights. Indeed, to create valid knowledge about systems as complex as a human body or an economy, people have to apply their current knowledge. Similarly, applying and preserving knowledge complement each other. Merely storing knowledge does not preserve it for long periods, because people must relate it to their current problems and activities.

Because all knowledge is imperfect and volatile, how knowledge evolves is more important than what knowledge exists. Fads and fashions serve as media for knowledge development and dissemination. They draw on aspirations, enthusiasm, fear, greed, mass media, social influence, and social pressure to encourage people to try new ideas. They make people aware that knowledge deteriorates, and they facilitate the discarding of obsolete ideas. The prevalence of many fads and fashions provides constant reminders that knowledge is transitory (Abrahamson and Fairchild, 1999). Change processes both produce knowledge and make it obsolete. People take new looks at what they have been doing, they develop new perceptions and make discoveries, some of which have lasting value. As a result, efforts to exploit new knowledge can improve organizational performance even if the new knowledge per se is not a significant improvement. People who are struggling with very difficult problems need visions of possible improvement to keep them going.

Changes in Information and Knowledge

Studies of organizational knowledge began to appear in the 1990s and they began to attract attention around 2000. The main stimuli for rising attention have been changes in evolving activities in developed economies, geographic migrations of economic activities, and technological innovations. Computers not only facilitate the processing of information but also provide metaphors for information processing by both individual people and social systems. Thus, equipped with an appropriate sense-making framework, managers and scholars began to notice the importance of information processing.

Information and knowledge have been growing in importance in developed economies and this trend seems likely to continue. The trend involves several components: (1) The developed economies are shifting away from manufacturing and toward services. For instance, in Europe, the telecommunications sector has been growing just under 14% annually, and the software and computing services sector has been growing by 15–20% annually. These changes have been occurring in part because agriculture and manufacturing have been migrating to developing societies. (2) The fastest-growing occupations have been clerical, professional, and technical workers, including managers and administrators. Professional-service organizations such as health-care agencies, law firms, and public-accounting firms have become much more important, grown much larger, and expanded globally. Knowledge workers and information workers are replacing manual workers. For example, machine-tool operators are giving way to technicians who monitor computer-controlled machines. (3) Workers of all kinds are gaining more education and more information-processing skills. Education, especially the higher levels of education that became prevalent during the last half of the twentieth century, has meant that more workers have valuable knowledge and more of them want jobs that allow

them to display or create knowledge. In the United States in 1900, only 14% of adults had completed 12 years of schooling. By 1998, 83% of adults had completed 12 years of schooling. Organizations have also been providing more education for their employees. Only 40% of the Americans who are receiving education are doing so in schools, and 60% are receiving it in their employing organizations. (4) Business is investing heavily in equipment for information work. In the United States in 2011, information-related equipment accounted for over 50% of capital investment. (5) Knowledge-intense and information-intense organizations are employing millions of people (Starbuck, 1992). (6) Corporations are depending on communications and information processing to keep them coherent as they globalize. Transoceanic communications have been growing about 35% annually, with the faster growth being in the Pacific region. (7) Firms are forming alliances and coalitions that rely on shared databases and electronic communication instead of face-to-face meetings. Business-to-business commerce has grown very rapidly during the early years of the twenty-first century.

Current thinking about strategic management emphasizes the usefulness of valuable resources that are rare and difficult to imitate (Barney, 1991). Both managerial and academic writings highlight the importance of knowledge to business success (Kogut and Zander, 1992; Nonaka and Takeuchi, 1995). Many organizations, not only the knowledge-intensive ones, seek to accumulate valuable and proprietary knowledge that they can exploit strategically. For instance, chemical and pharmaceutical companies employ skilled scientists and spend heavily on research aimed at developing patentable, proprietary products. Some manufacturing firms assert that cadres of experienced and highly trained managers comprise their key assets.

The policies of national governments have been changing the global distributions of expertise (Lewin et al., 2009). China, India, Singapore, South Korea, and Taiwan have been building capacity for knowledge-intensive work. For instance, China multiplied doctoral education in science and engineering by a factor of six between 1995 and 2003. Global corporations have been taking advantage of these plentiful and lower-cost resources by shifting their product development activities to these countries and away from the United States and Europe. At the same time, other countries – such as Canada, Europe, Latin America, Mexico, the Philippines, and the United States – have not built their capacity for knowledge-intensive work and they have not attracted it.

Knowledge Management within Organizations

Around 2000 managers and scholars began to pay much more attention to methods for managing organizational knowledge. Organizations have been trying to create knowledge management systems in order to store, create, transfer, and apply knowledge. Academic research in operations, information technology, economics, marketing, and management has proposed and analyzed ways to support the creation of new knowledge and to store and codify knowledge. Many firms have appointed learning officers who try to identify useful knowledge and to disseminate it to personnel who can use it. The University of Pennsylvania is offering a masters degree for people who aspire to become learning officers. Krogh et al. (2012) inferred that knowledge creation requires leadership that is distributed throughout an organization and that provides appropriate resources and structures.

Studies have suggested that three knowledge-management methods may be yielding benefits. All three methods focus on communication. First, some organizations are attempting to foster the conversion of tacit knowledge to explicit knowledge by organizing employees into on line communities that identify and discuss shared issues. Second, some organizations are attempting to disseminate knowledge by creating multiple channels for knowledge transfer and creating organizational cultures that advocate sharing. Third, some organizations are attempting to overcome the reluctance to share knowledge by adopting incentive pay systems that take account of overall organizational performance.

However, other knowledge-management methods face serious challenges that have caused them to disappoint their users (Calhoun et al., 2011). Several studies have documented knowledge-management efforts that proved unsuccessful. One central problem is the ambiguity surrounding knowledge and its value. What knowledge deserves keeping? Databases can easily grow so large that searching through them becomes very difficult. Indexing terms that appear useful today may make knowledge inaccessible tomorrow (Schultze and Leidner, 2002). A second central problem is that knowledge management techniques build on existing knowledge, so they are useful only as long as technological and social changes follow continuous, mainly linear trajectories. When technologies and societies make abrupt, nonlinear changes, knowledge-management methods are likely to impede organizations' efforts to adapt. A third central problem, related to the second, is that organizations, especially large ones, change slowly, so they need time to exploit new knowledge. To try to take advantage of the knowledge that is benefiting other organizations today is likely to yield disappointment because competitors are already exploiting that knowledge, so latecomers can hope only to catch up. Although current trends generally persist for a few periods, short-term benefits are likely to be small benefits. To extract large benefits from knowledge, organizations need to predict what knowledge will turn out to be beneficial a few years in the future.

Powerful organizations that collaborate with each other have advantages in predicting the medium-term future. Barnett et al. (2003) evaluated the accuracy of 3142 forecasts about US manufacturing industries that forecasters made during the 1970s. The studied forecasts concerned events that would not occur for at least 8 years into the future. The analysis found that forecasts about highly concentrated industries proved to be more accurate, especially forecasts about variables over which companies could exert stronger unilateral control. However, differences in the accuracy of forecasts were small in comparison with the wide ranges of errors that are typical of longer-range forecasts.

Abstract

This article starts with a brief history of information-processing architectures, emphasizing a traditional experimental paradigm, the additive factors method, and the classic problem of model mimicry. Several solid approaches to identifying mental architecture are introduced with a discussion of the necessary assumptions for these tests. Other fundamental issues attached to information-processing systems are also presented. A brief discussion with regard to challenges for the future concludes the article.

In the late nineteenth century, budding experimental psychology began to investigate perceptual and mental operations that would be considered part of the contemporary purview of cognition. Such interests reappeared in the 1960s in the emerging information-processing approach to elementary cognition. Over the last several decades, considerable progress has been made in this tradition through the combination of mathematical modeling and experimental design, an approach becoming known as metamodeling. This section reviews a number of selected findings within this approach, which is relatively novel in the social sciences. One benefit of the strategy is that potential dilemmas involving model mimicking, where models based on strikingly different principles can imitate each other's predictions, are brought to light. In particular, problems and experimental solutions associated with testing among parallel (simultaneous) versus serial (one-at-a-time) processing, stopping rules (logical basis for cessation of processing), limited versus unlimited versus Supercapacity (effects of increasing workload on processing speed), and dependence (issue of stochastic independence of channels or events) relationships are described. The foregoing issues are fundamental in almost all information-processing situations since virtually any operating system must take them into account. The section concludes by pointing to future challenges within this approach.

The term 'information-processing architecture' refers broadly to the arrangement of mental subsystems that are hypothesized to be active in the performance of one or more psychological tasks. For instance, the simplest, most prototypical, and opposed types of architectures are serial (one-at-a-time) versus parallel (simultaneous) arrangement of two or more separate subsystems or processes. More complex arrangements are mentioned below (*see Additive Factor Models*). Further, there are a number of other aspects of perceptual and cognitive processing that are often included under the 'architecture' label including the questions of the basis on which cognitive processes will cease, various kinds of independence and dependence, and processing capacity. These will be described and discussed.

An early researcher especially pertinent to this review was Donders, a nineteenth-century Dutch physiologist. Donders believed that he could uncover the durations taken by various thought processes through his method of subtraction. The method of subtraction was based on the idea that complicated mental activities were compounded in a simple sequential fashion from less complex parts. Let mean response time be written as $\overline{RT}$ and response time in general as simply RT. Then, for instance, the scientist might engage the subject in a task requiring both perception and decision and compare $\overline{RT}$ from that condition with $\overline{RT}$ from a task requiring only perception. The difference in $\overline{RT}$s was interpreted as the mean duration of the decision operation.

The issues selected for review here seem elemental in the following sense. The construction of almost any system intended to carry out the processing (e.g., detection, search, comparison, recognition, recall, analysis of various kinds, and so on) of a finite number of tasks or items would have to make decisions on each of the studied issues. In addition, they are somewhat unique in having been subjected to quite general theoretical, quantitative, and methodological analysis, perhaps more than any other such concepts in the field. The issues will be introduced in the context of a popular experimental paradigm and then discussed in more detail.

An Experimental Paradigm and the Major Issues

The concepts to be defined below have figured prominently in studies on short-term memory and visual display search and we shall employ that type of paradigm for illustration. Considerable impetus was given to the information-processing approach by several pioneering studies in the 1960s focusing on short-term memory and visual processing, using RT as the dependent variable (Atkinson et al., 1969; Egeth, 1966; Sternberg, 1966). In the roughly 50 years of the interim, scores and perhaps hundreds of studies in memory and visual search have been carried out. We focus on Sternberg's (1966) short-term memory search paradigm for illustration. Short-term memory is specified operationally by the tasks requiring the retention of a small number of items for anywhere from a few seconds to several minutes. In this paradigm, a varying number (less than or equal to the number that can be maintained in short-term memory without error) of items, for instance, randomly arranged letters, is presented to the experimental participant. This is called the memory set. Then, a few seconds later, that participant is presented a so-called probe item and the task is

to indicate very quickly, but at a very high level of accuracy, whether or not the probe was contained within the memory set. As introduced above, RT is the primary dependent variable of interest here, although a substantial history of work with accuracy also exists.

The first, and in some ways the most critical question, referred to the temporal structure of comparison of the probe item with the memory items. A hallmark of many early information-processing models was seriality of operation, that is, each subsystem or component could operate only when preceding mechanisms were completed and only one could operate at any given time. Thus, *seriality* has the connotation that no overlap of processing times occurs, in addition to the sequentiality of starting times. This latter type of constraint is referred to as *discrete flow*. The alternative possibility arose early on that all the items might be searched simultaneously, that is, in parallel. This issue of processing architecture can refer to the manner of treatment with regard to items within a single stage of processing, for instance memory search, as in the present case, or to the arrangement of larger components of the system, such as stimulus encoding versus memory storage.

Of course, arrangements other than serial versus parallel are possible, for instance, a system being serial part of the time and parallel part of the time. When all operations under focus begin at the same time but can finish at different times, the system (or mode of processing) is of course simply parallel. However, when operations can feed into other components, but with overlapping processing times, the system is said to have continuous flow, rather than discrete flow. A great deal has been learned about discrete-flow architectures of considerable complexity over the past two decades (*see Additive Factor Models*). We will confine ourselves to serial and parallel systems and other processing characteristics that these can involve.

The primary RT durations under study in the memory search task are those associated with comparison of the probe with the memory items. Nonetheless, other time intervals, such as those associated with early sensory processing and late motor components, must also be taken into consideration. It is usual, but by no means uncontested assumption, that these so-called residual times are serially arranged with and stochastically independent from the process under study (Dzhafarov, 1992; Luce, 1986; Townsend and Ashby, 1983).

Besides the architecture issue, independence versus dependence among the processing times of the items is also an important question. For instance, in serial processing, if an earlier item takes more time than usual, a subsequent item might consume less duration due to more preparation time, resulting in a negative dependence among processing times. On the other hand, positive dependences are possible. An example would be a positive dependence created somewhat artificially if *attention* available on a trial were a random variable, for then the items would all tend to be processed quickly or slowly more or less in unison. Analogously, parallel systems can either be constituted with independent channels (e.g., Bundesen and Habekost, 2008; Eidels et al., 2010) or with positively (e.g., Townsend and Wenger, 2004b; Wenger and Townsend, 2001) or negatively (e.g., Usher and McClelland, 2003) interactive channels.

Another critical concept is that of *workload capacity* (or 'capacity' for short if the meaning is clear), which refers to how processing times are affected by the number of things to be worked on (Townsend and Ashby, 1983). This is most easily illustrated with a version of parallel processing where the system slows down when the number of items that are being processed increases (i.e., limited capacity). However, limitations in capacity that are indirect, even with serial processing, can be conceived. For instance, a serial processor might speed up as it goes through the items, due to warm-up effects, or slow down due to inertial factors or fatiguing of the processor. Even though capacity and independence are logically separate notions, they can interact. For instance, an important type of parallel system, one that can mimic serial processing, assumes that as the processing of each item is completed, its processing capacity is reallocated to remaining items (Townsend and Ashby, 1983). This obviously affects the overall RT, but also creates a positive dependence among the item processing times. Townsend and Wenger (2004b) built a theory and associated methodology featuring the capacity theme.

Yet another important notion is that of stopping rule (e.g., Sternberg, 1966; Townsend, 1974). Depending on the task, it may or may not be necessary for the system to process all of the items in order to make a correct response. In the memory search paradigm, if the probe item is present and located in the current stimulus set, the processing can cease at that instant, without finishing the remaining items. This event is known as self-termination. However, because short-term memory search consumes only a few hundred milliseconds it is possible that the system nevertheless completes all items. This event is called *exhaustive* processing. On probe-absent trials, it is necessary to process all of the memory items to be sure of correctly making a 'no' response, that is, exhaustive processing must occur. In some experimental designs, all the items are probes. These need not be physically identical. For instance, the task might be to say 'yes' if any of the items is a vowel and a target-present trial could contain all vowels. This latter case permits the possibility of *first-terminating* or *minimum time* processing. Of course, it is an empirical question as to whether any kind of self-termination can actually take place in high-speed perceptual or cognitive operations, and must be addressed experimentally in each case.

Space constrains the scope of mathematical detail in the present article, but we provide some fundamental, if simplified, depiction. Although the serial and parallel classes of models both contain an infinite class of possibilities, the serial notion has traditionally been attached to a particular serial model that assumes identical processing time random variables on each item, independent of the number of items in memory (i.e., the load) and of the order of processing the items. It is also often assumed that the individual processing times are themselves mutually stochastically independent. We call this the *standard serial model*. Let the density of processing time for each item be designated $f(t)$ and that for the independent residual processing time be $r(t)$. Then the density on a probe-absent trial, $p(\mathrm{RT} = t)$, or $p(t)$ for short, is just the mathematical convolution of the n processing densities and the residual time density:

$$p(T|EX) = r * f_1 * f_2 * \ldots * f_n$$

where each f_i, $i = 1,\ldots, n$, is equal to f. The expected or average theoretical RT is $E(\mathrm{RT}) = n \cdot E(T) + E(R)$, where T and R are the respective random variables for individual item-processing time and residual-processing time. Notice that processing is exhaustive, as designated by EX in the left-hand side, in this case. In the case of self-terminating (ST) processing on a probe-present trial, the number of items finished before the probe is found is itself a random variable. Under usual conditions, the probability that the probe will be found in the i-th processing position is just $1/n$, so the average density for this case is just.

$$E[p(RT|ST)] = [(1/n)\sum_{j=1}^{n} f_1 * f_2 * \ldots * f_{i-1} * f_i] * r$$

Similarly, the expected RT, with $\overline{\mathrm{RT}}$ as the sample statistic, is just

$$\begin{aligned} E[(\mathrm{RT}|\mathrm{ST})] &= (1/n)\cdot \sum_{j=1}^{n} jE(T) + E(R) \\ &= [(n+1)/2]\cdot E(T) + E(R), \end{aligned}$$

which yields the time-honored result that this line has half the slope of that for the exhaustive serial RT.

The concept of parallel processing, like serial processing, is usually confined in the experimental literature to a very special kind of parallel processing. Processing is often said to be parallel if average RT is invariant across increases in load. When exhaustive processing has to occur, as in the probe-absent trials of memory search, this stipulation actually implies a very unusual kind of parallel processing, unlike the situation with the standard serial model. For instance, consider a set of parallel models with independent processing times, with the additional provision of unlimited capacity, in the sense that the probability distribution on completion times for each item does not change as n is increased. This class of models serves as a prototype of parallel processing in an analogous way to the standard serial model class just presented. Let us call this class the standard parallel model.

Let $g(t)$ be the fixed density function on processing time for each of the n items. Then $E[\mathrm{RT}|\mathrm{EX}] = \mathrm{E}\{\mathrm{MAX}[T_1, T_2, \ldots T_{n-1}, T_n]\} + E(R)$, where R is the residual time as above and T_i is the processing time of the item in position i. We drop reference to R which plays no role in the function shape, letting PT stand for processing time, that is, $\mathrm{PT} = \mathrm{RT} - R$. Then $E[(\mathrm{PT}|\mathrm{EX})] = \int_{-0}^{\infty} [1 - G(t')]^n \mathrm{d}t'$, where $G(t)$ is the cumulative distribution function associated with g. It is straightforward to show from this formula that mean RT is indeed an increasing, concave function of n (Townsend and Ashby, 1983, p. 92). Note that $g(t)$ is invariant across values of n. Hence, many investigators use a very restrictive and typically unrealistic criterion for parallelism when they demand flat rather than increasing functions $\overline{\mathrm{RT}}$ of n, even under exhaustive processing conditions.

It can also be observed that if mean exhaustive $\overline{\mathrm{RT}}$s are flat functions of n, then mean ST (again, a single position exists in the memory list that contains the probe) processing times would actually be decreasing, within the same model – a strong prediction which apparently has never been checked in studies using this logic. Thus, in the rare cases where flat exhaustive $\overline{\mathrm{RT}}$ functions are actually found with exhaustive processing, the implications are quite strong and in favor of very supercapacity parallel processing. Models that can make such predictions are considered in Townsend and Ashby (1983, Chapter 4).

In contrast, in the case of ordinary ST processing when a single position contains the probe, standard parallel models do predict a flat $\overline{\mathrm{RT}}$ function. This can be readily intuited, since only the channel that processes the probe matters in ST processing, and it is independent of all the rest (and is of unlimited capacity into the bargain). Finally in this model, mean first-terminating times should decrease with n.

Important Related Research Topics

Although the issues considered here are applicable to virtually any information-processing system or task, there are some classical or contemporary subject areas for which they are particularly germane.

When applied within the confines of a single subprocess, such as search within a memory or display list, the concept of attention is evoked. How attention is deployed, when it ceases, whether its application is independent across the various items, and its strength as a function of the workload, all call upon the critical processing issues introduced above.

The topic of *automatic processing* or automaticity, traditionally discussed within the realm of attention, likewise overlaps our present issues (e.g., Schneider and Shiffrin, 1977). The most obvious correlate within our processing issues is that of capacity. Although writers are sometimes rather vague concerning detailed quantitative accounts of what automaticity means with regard to workload capacity, it seems apparent that parallel processing is definitely mandated. In addition, we have proposed that capacity should at least be at the unlimited level. That is, each subsidiary task should see its operations proceed at the same speed as if it were functioning alone. These and related matters are discussed further in Neufeld et al. (2007).

Another traditional theme also seeing resurgence is that of perceptual and cognitive *holism*, a topic of long standing interest in philosophy and, in the twentieth century, of *Gestalt psychology*. Although much has been learned about psychological holism, there has been little accomplished with regard to definitions, theory, and experimental investigation of information processing characterizations of dynamic holistic operations. In that spirit, a set of working axioms which portray holistic perception in terms of the present issues have been proposed and developed (e.g., Wenger and Townsend, 2001; Wenger and Ingvalson, 2003; Fific and Townsend, 2010). The accompanying essentials of holistic perception can be informally expressed as involving highly interactive, supercapacity, exhaustive and parallel processing.

The Mimicking Dilemma of Serial versus Parallel Processing

As mentioned earlier, one of the driving forces behind mathematical metamodeling in this area was the discovery that

mathematical representations of diametrically opposed psychological principles could nevertheless sometimes mimic one another, even to the point of mathematical equivalence of their defining probability laws (Murdock, 1971; Townsend, 1971; Townsend and Ashby, 1983). A historical account of this dilemma and its resolution is offered by Townsend et al. (2011). Hence, we will take some time here to outline the state of the art with regard to such questions within the parallel versus serial question.

Consider a model for the processing times of n items under fixed experimental conditions. With regard to the parallel–serial issue, suppose no assumptions are made other than the probability mixture of generalized convolutions in the case of seriality and joint distributions on processing times in the case of parallelism. Then the parallel and serial classes of models are equivalent, in the sense that mappings can be provided that homeomorphically (this is mathematical jargon for a one-to-one and bicontinuous function relating the two types of models) carry the serial probability distribution into the parallel probability distribution and vice versa (Townsend and Ashby, 1983).

Nevertheless, over time, accumulating theoretical results have demonstrated that if the scientist is willing to make further restrictive, but sometimes still very general (and reasonable), assumptions about the models, and/or more complex experimental designs are utilized, the parallel–serial issue can be decided. For instance, certain rather fundamental differences between serial and parallel processing can be explored in experimental methods designed to exploit those differences (Townsend and Ashby, 1983; Townsend and Wenger, 2004a).

Factorial Methodologies for Architectures and Systems Factorial Technology

One of the most promising and general approaches to identifying mental architecture (i.e., serial versus parallel processing) is that based on the notion of *selective influence* of experimental factors, a notion first employed in tests of strict seriality by Sternberg (1969) in his well-known additive factors method (*see Additive Factors Models*). All factorial methodologies, like the original Sternberg strategy, depend on the selective influence assumption, namely that distinct experimental factors affect distinct processing components (i.e., subsystems). It can be assumed that $\mathrm{RT}(X+\Delta X,\ Y)$ refers to the case where the X factor has prolonged RT but Y is at base level, and so on. Basically, the fundamental statistic for the original method and for most extensions was the *mean interaction contrast* (MIC). The MIC is defined as

$$\begin{aligned}\mathrm{MIC} = {} & \overline{\mathrm{RT}}(X+\Delta X, Y+\Delta Y) - \overline{\mathrm{RT}}(X+\Delta X, Y) \\ & - [\overline{\mathrm{RT}}(X, Y+\Delta Y) - \overline{RT}(X, Y)].\end{aligned}$$

Schweickert (1978) in his *latent mental network theory* contributed the first major extension of the additive factors method involving more complex architectures under the assumption of selective influence. Townsend and Ashby (1983) found that the MIC distinguished parallel and serial stochastic models when selective influence was assumed and Schweickert and Townsend (1989) produced general theorems for Schweickert's latent networks, within a stochastic setting, assuming exhaustive processing (see *Additive Factor Models*; Network Models of Tasks).

Although the early theorems in all this work were accomplished in the context of exhaustive processing, analogous results can be found in the case of ST and first-terminating processing times (e.g., Townsend and Nozawa, 1995; Townsend and Wenger, 2004a). Because Sternberg's original ideas inherent in his additive factors method have been extended in so many new directions, it has been suggested that the general approach be referred to as systems factorial technology (Townsend and Thomas, 1994). For instance, one novel strategy has been to enlist entire RT distributions in providing more powerful tests of parallel versus serial processing or other related architectures (Dzhafarov and Schweickert, 1995; Roberts and Sternberg, 1993; Townsend, 1990; Townsend and Ashby, 1983; see also Balakrishnan, 1994). For instance, in analogy to the MIC, the scientist can form a contrast function composed of the double difference (corresponding to the double difference in mean RTs in the usual case) of cumulative distribution functions. This new statistical function turns out to be very helpful in assaying mental architecture (Townsend and Nozawa, 1995). Another example of the use of entire distributions will be reviewed below.

The assumption of selective influence is critical to the legitimacy of systems factorial technology. Much has been learned in recent years about its foundational underpinnings, what may go awry if it is violated, and about certain experimental indications of its failure (Dzhafarov, 1997; Dzhafarov and Kujala, 2010; Townsend and Schweickert, 1989; Townsend and Thomas, 1994).

Discriminability Results on Stopping Rule, Capacity, and Dependence

The question may be raised as to whether processing issues other than parallel versus serial processing also suffer significant problems in identification within the search or related paradigms. With regard to the stopping rule, mathematical investigations have shown, somewhat ironically, that the same types of memory search data that were incapable of deciding the parallel–serial question could in many instances prove that processing was ST rather than exhaustive. Interestingly, it is more difficult to prove that processing is exhaustive in that ST models can mimic exhaustive processing but not vice versa (Townsend and Colonius, 1997; Van Zandt and Townsend, 1993).

Moreover, recent theoretical and empirical discoveries utilizing the entire RT distributions rather than means provide much strengthened tests of architecture (parallel versus serial) and in addition allow one to firmly distinguish stopping rules at the same time. In fact, within systems factorial technology and assuming selective influence at the distributional level, Townsend and Nozawa 1995 (see also Townsend and Wenger, 2004a) proposed an experimental design that they called the *double factorial paradigm* in which investigators can test architecture and stopping rule as well as capacity within the same block of experimental trials.

Additionally, the important matter of workload capacity seems to possess little in the way of mimicking predicaments.

Whether capacity increases, decreases, or is invariant in the face of workload alterations is immediately captured by the current statistical measures.

The most difficult issue of the ones under discussion is that of stochastic dependence, even though it plays a vital role in processing systems. Interestingly, at this point in time, dependence is more readily and more directly assessed within experimental designs based on accuracy rather than RT (Ashby and Townsend, 1986; Kadlec and Townsend, 1992).

Challenges for the Future

The bringing together of mathematics and experimental methodology has lead to a useful stratagem that we call metamodeling. Systems factorial technology provides an example of metamodeling. Metamodeling facilitates the development of experimental methodologies that are capable of testing broad classes of models, rather than highly specific models, against one another. This approach is especially helpful when attempting to settle well-defined issues, for example, diametrically opposed concepts such as parallel versus serial processing. It may be more difficult to use this strategy with highly complex and detailed models of phenomena (e.g., Van Zandt and Ratcliff, 1995).

Metamodeling has arguably led to striking advances in the ability to decide experimentally a number of elementary, but major, issues in the purview of human information processing over the last several decades of the twentieth century. Some of these were outlined above. However, many challenges remain. For instance, long-standing challenges relate to the somewhat pesky residual time component introduced earlier. It is difficult to know in many cases how successful our various strategies can be until its nature is firmly tied down. As noted earlier the residual time is usually assumed to be in series with, and stochastically independent of, the other processing components (Luce, 1986; Smith, 1995; Townsend and Ashby, 1983). However, this assumption may be and has been challenged. Thus, it has been contrasted with the extreme opposite assumption of perfect correlation, but still within a series arrangement of the residual component with the other stages of processing (Dzhafarov, 1992; see also a specific case of apparent nonindependence, Diederich and Colonius, 1991).

The most time-honored approach has been to attempt to separate the residual time component from those under study employing Fourier analysis, assuming stochastic independence of these components. This has proven to be a tricky and arduous strategy. Luce (1986) and Sheu and Ratcliff (1995) provide useful reviews and commentaries on this approach. Another kind of powerful, if often difficult, approach regarding the residual time component has been to prove that experimental predictions hold true regardless of its presence (Dzhafarov and Schweickert, 1995; Roberts and Sternberg, 1993; Townsend and Ashby 1983).

The residual time problem also abuts a more general possibility, namely that processes in the same forward sequence may not satisfy discrete flow, but rather obey continuous flow properties. For instance, almost all systems based on differential and integral equations would fall into the continuous flow class. Some intriguing progress, both theoretical and empirical, has been made on certain subclasses of such systems (McClelland, 1979; Miller, 1993; Schweickert and Mounts, 1998), but much more remains to be done.

Another evident opportunity for development is the extension of factorial methods in general, and systems factorial technology in particular, to other dependent variables than response times. The most palpable extension would be to accuracy or accuracy and response times. Another interesting and topical subject matter would be *confidence ratings*. In this regard, it has been pointed out that it constitutes a grave error to simply assume that predictions for response times will also apply to other observable variables (Townsend, 1984). Theorems that are appropriate for specific observables within an information processing milieu must be proven and tested in the experimental crucible.

As a final example that is offered is that of implementing the concept of a theoretical and methodological *sieve*. Within such a sieve, the investigator first establishes the major processing characteristics of information processing in a cognitive task, and then proceeds to propose and test more computationally detailed accounts that are in accord with the earlier findings. The methodological sieve is related to, but is more general than, the concept of *strong inference* put forth by Platt (1964) (e.g., Massaro, 1998).

Abstract

The concept of the information society is a master key for both social-scientific interpretation of contemporary society and sociophilosophical articulation of normative and public-policy issues. It expresses 'informatization' – translation of the Japanese original, 'johoka' – a manifold sociotechnical process involving postindustrial economic shifts, opening of institutions, information and knowledge explosions, and, especially, the rapid diffusion and phenomenal impact of new information and telecommunication technologies. This article examines canonical sources of what became known as the information society thesis, notably the prescient ideas of the late polymath Daniel Bell, criticisms of the thesis, and a selection of salient information policy challenges facing twenty-first century democracies and global organizations.

Introduction: Informatization and the Information Society

The idea of the 'information society' has emerged as a master key capable of unlocking numerous salient developments in the entire arc – economy, culture, and polity – of postindustrial societies, and indeed of the world, conceived as a global, interconnected community. The underlying claim is essentially very simple, that information in its various dimensions, modes, and phases, including, but not confined to, information and communication technologies (ICTs), has played a leading role in the transformation of human engagement with almost all domains of life, to such an extent that it is now valid to refer to advanced nations as information societies. While information has of course always been vitally important to social existence, it is now somehow center stage. The sense, not yet complete but apparently well underway, of a reconfigured sociotechnical order, a new form of being in the world, perhaps even an embryonic information-conscious global civilization, is what gives increasing purchase to the smart catchphrase 'the information society.'

A closely related concept is 'informatization.' Underutilized in the West, this awkward neologism has the advantage that it denotes a process rather than a product, thereby facilitating modulated, evidence-driven discussion about the extent and character of the changes afoot, without necessarily enforcing endorsement of stark propositions about a new society. 'On the one side,' as Frank Webster observes in *Theories of the Information Society*, "are subscribers to the notion of an information society, while on the other are those who insist that we have only had the *informatisation* of established relationships" (2006: p. 6). The information society concept is likely to remain controversial deep into the millennium, pitting believers against sceptics, revolutionists against evolutionists, optimists against pessimists, technological determinists against social determinists, even political right against left. Some of these axes will be examined below.

The process of informatization is extensive, multifaceted, and conflictual. It includes not just the spread of new ICTs in line with standard models of diffusion (Rogers, 2003), but the superseding of manufacturing industry by economies geared predominantly to services and myriad information-based occupations; explosive growth in news and other media content and outlets; the worldwide official trend in favor of disclosure, open institutions, and freedom of information; a less visible, gradual, and in many ways countervailing movement toward the commodification, classification, or encryption of data; unceasing expansion of scientific journals and other scholarly documentation; the phenomenon of 'grassroots' or 'wild' information flows, of which Wikileaks has been the preeminent exponent; and no doubt other, as yet unregistered, information-related developments quietly gathering strength behind the scenes.

One could argue that informatization, broadly understood in such ways, is a fundamental social principle, a motor of modern economic and political development. This is why scholars have been led to refer to the 'informatization of the world view' (de Mul, 1999) and to posit the existence of an 'info sphere' (Floridi, 2007: p. 59) – in more antique language, informatization seems to represent 'the spirit of the age.' It should be noted that the tendency to equate informatization and information technology is unhelpful, since the relation of many aspects of informatization to computers or telecommunications is contingent rather than logically necessary. Nevertheless, there can be no doubt that electronic and specifically digital technologies have played a decisive part in the contemporary informatization process, and that the arrival of personal computing and then the Internet is what precipitated the widespread consciousness of a transition to an information society.

At the root of the information society debate is the basic meaning of the word 'information.' There have always been two separate – overlapping, but essentially different – conceptions. The first is the technical conception seminally expounded in Claude Shannon and Warren Weaver's *Mathematical Theory of Communication* (1949). More commonly known as information theory, this field is dedicated to analyses of the conditions of efficient telecommunication, of getting information from senders to receivers with a minimum of erosion or 'noise.' Information here means message, any kind of communicable signal, but its content is immaterial. It must be measurable – must be capable of being cashed into and back out of binary digits – but it need not be intelligible. "Information," Shannon

and Weaver confirmed (1949: pp. 8, 31), "must not be confused with meaning," because "semiotic aspects of communication are irrelevant to the engineering problem." Information theory is recognized as an intellectual pillar of the postwar epoch, one that has assisted the development not only of computing and telecommunications, but also of cryptography, the theory of stock market investments, and numerous other branches of applied knowledge. Indeed, in this catholic sense, information has installed itself as a preoccupation of fundamental disciplines at a great remove from the social and behavioral sciences, such as physics and biology; it is arguably even, as one thinker vividly puts it, 'the new language of science' (von Baeyer, 2004).

However, this is by no means the ordinary-language meaning. In common parlance, information denotes meaningful messages, and, moreover, accurate and useful ones – facts, news, statistics, official reports, astronomical data, bank statements, rail timetables, and the like. When we ask for flight information at the airport desk, we do not expect to receive misdirections, still less to hear, say, a rousing rendition of 'Pretty Vacant.' Unfortunately, much of what cascades through the ubiquitous, ever-expanding channels of the global information infrastructure is information only in the minimal, Shannon–Weaver sense. It consumes disk space and clogs up networks, but as often as not it is substantively uninformative: it is phatics, pointless phone calls, palpable falsehoods, pornographic imagery, or plain gobbledygook. If, therefore, we are going to build an information society on solid foundations, a civilization of which we can be justly proud, we probably need to start with a great deal more clarity about what we wish to count as real information.

Whatever its semantic and other issues, information society rhetoric has swept through policy and official circles at all levels. It is difficult to find a country – even in the developing world – which has not at some point in the past promulgated its own information society plan, usually a wish-list about computerization and the 'wiring' of economic growth. At a regional level, the European Commission since the 1990s has heavily exploited the concept in its drive both to privatize and deregulate telecommunications, and to foster pan-European solidarity among citizens; Brussels now houses a dedicated Information Society and Media Directorate. Similar ventures were launched, although with less success, in Africa and other regions. Global bodies have also been active. The Organisation for Economic Co-operation and Development has invested enthusiastically in the promotion of information society indicators. The G8 flirted. However, the most significant global effort was the World Summit on the Information Society, which in 2003 and 2005 convened senior representatives of the nations to address pressing policy issues, such as Internet governance and the digital divide. The paramountcy of the information society phenomenon can thus no longer be denied; and there will presumably need to be more such summits to debate the future of the only planetary resource whose supply is literally inexhaustible.

A Canon of Information Society Studies

Some, especially the young, perceive the information society to be so natural that it does not need interrogation. But while from infancy they can 'surf' cyberspace and as teenagers some can dazzle with technical jargon, they often fail to grasp how the Internet really works, still less comprehend the invisible drivers of the wider information society. Rather than parading their online transactions, these 'early adopters' (Rogers, 2003) perhaps need to ask whether they are not puppets subject to "the soft compulsion of constant consumption training" (Jurgen Habermas quoted in Webster, 2006: p. 167). They are usually surprised to hear that scholars have been thinking about the information society for at least half a century, spotting trends, anticipating problems, mapping future scenarios. The present section introduces the main pioneers of what became known as the information society thesis, and seeks to explain precisely how each advanced this intellectual cause. While explicit talk of canonicity has not yet engulfed this most ecumenical and interdisciplinary of specialties, volumes of 'key readings' and 'classic texts' are common enough. At risk of premature closure, then, the following can be construed as a canon of information society studies (Duff, 2000; Raban et al., 2011).

Credit for launching the information society thesis must be given to Fritz Machlup. Machlup (1902–1983) was a classically trained economist, an émigré from Vienna who became one of America's most distinguished professors. It was while pursuing more or less routine research on the economics of patents that he had his 'Eureka moment.' Perusing, no doubt for the umpteenth time, some standard statistical tables, he suddenly saw that a great portion of the value of the US economy, and the occupations undergoing the fastest growth, were involved in either the production or the distribution of knowledge – broadly defined. The core of the world's leading economy, according to *The Production and Distribution of Knowledge in the United States* (Machlup, 1962), consisted not in agriculture, automobiles, or oil but in the intangible goods and services of the mind. Education was now a huge 'industry,' worth some $60 000 000 000, if one included not merely classrooms but training on-the-job, Sunday schools, and public libraries. Research and development, although more modest in terms of employment, was still worth $11 000 000 000, even disregarding its multiplier effects on the rest of the economy. The other major knowledge industries were information services, communication media, and information machines, all of them expanding aggressively. IBM was still mainly building typewriters, but Machlup was quick to note the 'ascent' of the computer, 'this amazing machine' (1962: pp. 306–307).

All in all, the knowledge economy accounted for $136 000 000 000, or nearly 30% of the US Gross National Product. It was a revelation, what looked like the makings of a bona fide paradigm shift. Reviewing the book, Kenneth Boulding, himself a leading economist, opined that "the very concept of a knowledge industry contains enough dynamite to blast traditional economics into orbit." In the event, mainstream economics preferred to continue in its normal conservative tracks. However, Machlup's work did eventually lead to the flowering of a new technical specialty called the economics of information, associated now with other luminaries such as the Nobel Laureates Kenneth Arrow and Joseph Stiglitz; and on a wider front, it had a permanent and salutary impact on the academy and beyond. Machlup himself assiduously pursued his new research front, his final service being the editorship of

an unfinished multidisciplinary oeuvre entitled *Knowledge: Its Creation, Distribution, and Economic Significance* (Machlup and Mansfield, 1980–1984).

Marc Porat also belongs in the canon. He is cited almost as much as Machlup, although he did not produce a single book, just an excellent PhD dissertation, which turned into a government report (Porat, 1977). He then disappeared from academic trace, resurfacing later as an information technology entrepreneur. Yet Porat's contribution to information society studies was substantial. He established the vocabulary of 'information economy,' 'information society,' and 'information policy,' pushing aside Machlup's talk of knowledge. He also rationalized the various categories of information jobs. In particular, Porat showed that there are really two types of information economy, the primary, composed of people, such as journalists and librarians, who engage directly with information, and the secondary, comprising workers who deal with it behind the scenes, in industries which are not as a totality classified as information industries. Administrative staff in a garage are illustrative of the latter, but Porat also included less obvious occupations: half of professional nursing, for example, he argued, was devoted to advising, recording, and other information activities. He then forecast, correctly, that workers in the US primary and secondary information economies would by 1980 outnumber manual workers. Finally, writing well after the publication of Machlup's classic, Porat was in a position to give information technology the place it now deserved. 'The foundation,' he declared (Porat, 1977: p. 205), "of the information economy, our *new* central fact, is the computer."

The third and greatest figure, in what was a pioneering western triumvirate, is the late polymath Daniel Bell (1919–2011). A professional journalist before becoming a sociologist, Bell was able not just to offer broader social-scientific perspectives on the technical and economic changes underway, but also to turn them all into a compelling narrative, a feat he accomplished definitively in *The Coming of Post-Industrial Society* (1973). Bell's central claim, first voiced at a European seminar as early as 1959, was extremely bold: the industrial era, no less, was passing away and a new world being born, one based not on manufacturing but on the provision of services, especially those of the human and professional varieties. Whereas labor in developing countries was a harsh 'game against nature' and in the industrial regions a 'game against fabricated nature,' in postindustrial societies life and work were becoming largely a 'game between persons.' And at the center of this socioeconomic shift was information and knowledge. "What counts," he pithily wrote (Bell, 1973: p. 127), "is not raw muscle power, or energy, but information." In particular, the highly refined form of information that is science – 'theoretical knowledge' – is the axial principle driving advanced societies, its progress facilitated by 'intellectual technologies' like cybernetics, forecasting, and decision theory. The computer had a starring role in Bell's account too, especially in later formulations; this information machine was, he wrote in an influential, Machlup- and Porat-citing, essay entitled 'The Social Framework of the Information Society' (Bell, 1980: p. 509), "the 'analytical engine' that has transformed the second half of the twentieth century." And presiding over the whole show, according to one of Bell's most controversial theses, was a new, meritocratic knowledge class, a replacement for the power elites of bygone eras.

In *The Cultural Contradictions of Capitalism* (1976), Bell explored, in masterly prose – he ought to be remembered as one of the finest prose-stylists of his day – the implications of this technoeconomic paradigm shift for the social order. The traditional, heavily ideological struggle between labor and capital, he suggested, was being overwritten by new kinds of conflicts, for example, between the capitalist economy's norms of self-discipline and 'delayed gratification' and the rank hedonism of modern bourgeois culture. Bell accurately foresaw major power-struggles over privacy, the funding of higher education, and intellectual property. He also bravely problematized the western intelligentsia's war on religion and universal values. Yet this prophet's vision was at heart progressive and futuristic – indeed, Bell is also often credited as the father of futures studies – and his optimism has proven to be the prevalent mood among commentators on informatization.

The Japanese are often underestimated in these Sinocentric times, yet they actually coined the terms informatization, a translation of the Japanese word 'johoka,' and information society, or 'joho shakai.' It is in some ways not surprising that Japan, a country reeling from nuclear assaults and enjoying little more than tuna fish in terms of natural resources, should look to rebuild its economy on the intangible, undepletable asset of information. As early as 1968, Japanese researchers were quantifying the so-called information explosion, and from 1975 the government ministry of posts and telecoms began conducting a regular, large-scale information flow census. Using words as their unit, they demonstrated empirically what everyone sensed intuitively, that the supply of information had indeed greatly outstripped our capacity to consume it, and that this was largely due to the dramatic expansion of electronic media (Ito, 1981, 1991). It was also this research programme that first established the existence of a trend from mass communication to point-to-point, personalized information flows, what they called 'bunshu shakai' (segmented information society) – the latter now of course a dominant feature of the social network-laden info-communications landscape of the twenty-first century. The information explosion continues apace, now having to be measured in zettabytes (sextillions, or 10 to the power of 21) and even yottabytes (septillions, power of 24) (Hilbert, 2012).

It is certain, therefore, that the Japanese deserve a niche in the canon. Who else gets in is more difficult. However, one name unlikely to be disputed by any of the disciplines and factions, is that of Manuel Castells. His trilogy *The Information Age: Economy, Society, and Culture*, already into its second edition, has brought much of value to the theory of the information society – or, to be more precise, to the theory of 'informational society,' the heading he reserves for the new social form, on the grounds that all societies throughout history have been to some extent information societies. Castells has unabashedly made 'the information technology revolution' – title of volume one, chapter one (Castells, 2000) – the cornerstone of his analysis. He has correctly highlighted the key role of networks, both digital and offline. He has also internationalized the thesis, moving away from the triumvirate's focus on the United States to encompass developing as well as advanced countries.

This allows him to treat the effects of ICTs on dispossessed groups as diverse as al-Qaeda and the Mexican Zapatistas. The result is a major sociocultural thesis about how modernity and technology are forcing some communities into a resurgent, resistant politics of identity: the Net, as he puts it, vs the Self. Reflecting a more radical political outlook than Bell's, Castells makes the plight of the whole world his parish. In the world's 'back alleys,' he concludes with characteristic verve, "I have sensed the embryos of a new society" (Castells, 2004: p. 428).

Finally, brief mention should be made of the unfinished work of the much-mourned Rob Kling (1944–2003). He founded social informatics, "the body of research and study that examines social aspects of computerization—including the roles of information technology in social and organizational change and the ways that the social organization of information technologies are influenced by social forces and social practices" (Kling quoted in Berleur et al., 2006: p. 1). Although many scholars within social informatics tend to concentrate on the meso- and microlevels, shying away from more complex and demanding macrolevel debates, Kling himself was more adventurous. A disciplinary migrant from computing to library and information science, he oversaw groundbreaking research studies on the societal impact of computerization. Equally importantly, as an energetic editor of *The Information Society*, the first and, alongside *Information, Communication & Society*, the leading journal in the field, he moderated a high-profile space in which a richly textured, politically sophisticated information society debate could materialize.

Critiques of the Information Society Thesis

While an information society perspective, however raw, has gradually imposed itself on much of officialdom, it has not been without opposition in the academy. Some of the objections have been philosophical, others sociological; in addition, sections of the political left have maintained a dogged rear-guard action against central claims surrounding informatization and the information society – for them, the thesis is little more than a smoke screen for contemporary capitalism. The following paragraphs outline the chief criticisms and some standard responses.

The first, philosophical or perhaps sophistical, is about the cutoff. It asks at what point industrial society metamorphoses into information society, and insinuates that any such specification will be unjustifiable. This seems like a version of the ancient 'heap' paradox. There is a heap of, say, 100 stones. Take away one and it remains a heap. Take away two and it is clearly still a heap. But it gets trickier as one goes down, and eventually, the Greeks argued, one is forced into either saying that one stone constitutes a heap or making an arbitrary judgment about when to stop. The response to this is simply that in the context of informatization the tipping point is the unexceptionable yardstick of a majority. A nation becomes an information society when over half of its labor force can be credibly designated as information workers, and this point has already been reached in numerous western nations. If the objections were valid, it would count equally against the industrialization thesis, according to which preindustrial economies graduate eventually into industrial ones. But if no one is disputing the industrial revolution, why should anyone dispute the information revolution?

Another charge is that the information society thesis is trivial, if not downright tautological. The key variable, information, it is contended, is too vague, too all-encompassing. The information sector might well be over 50% of the economy, but only when it is defined so loosely as to be drained of much of its significance. Indeed, sociologists have joked that the definition is so liberal that it includes fortune-tellers and even 'strip-tease' dancers. Yet against this one just has to set the painstaking, blow-by-blow analyses of Machlup, Porat and their school. Exactly which of their categories is being impugned? Surely not education? Surely not R & D? Surely not people who work with computers and other information machines? As for other occupations, was Porat so mistaken in his decision to include half of nursing? Anyone familiar with the intricacies of modern nursing would have no problem with that. Dancers, subsumed in Machlup's category of communication media, along with the rest of the entertainment industry, admittedly seem more brawn than brain. Yet even if we score off this numerically, if not always morally, modest trade, that is hardly going to overturn the entire information society thesis. The accumulation of evidence for informatization, as regards not just the work force but also the exponential communications explosion and other vectors mentioned above, is now so strong that legitimate questions over particular inclusions should not blind us to its essential validity.

A further persistent charge has been that information society exponents are guilty of hyperbole, of outlandish assertions. While claims of partial informatization can be accepted, those alleging social revolution – propositions about a total transformation of society – are erroneous and dangerous. It must be admitted that some have talked in such a manner. "The information epoch to be brought about by computer-telecommunications technology," announced Japan's Yoneji Masuda (1981: p. 51), "does not simply mean that it will have a big socio-economic impact upon contemporary industrial society; it will demonstrate a force of societal change powerful enough to bring about the transformation of society into a completely new type of human society, which is the information society." Bell himself was also often accused of sensationalism and utopianism, despite his having explicitly distanced himself from the 'star-trek sociology' of some fellow travelers. The lesson is simple. It is essential when assessing the information society thesis to make a clear distinction between core and peripheral claims. Bell's core claim about the coming of postindustrial society is, as regards occupational structure and some other aspects of the socioeconomic system, now vindicated. In this sense, the headline 'the information society is here' is no exaggeration. Some of his concomitant assertions, about scientific knowledge driving social policy or the ascendancy of a new political class, are equally clearly mistaken, or at best premature. The same medicine can be applied to other information society theorists.

Many leftists have seen the use of the information society concept as somehow ideological or propagandistic. Behind the progressive technological scenarios – glib talk of

'computopia,' for example – lie, they insist, conservative economic scenarios. Much of the early animus against Bell, according to which this Marxist-turned-social democrat was "advanced capitalism's most persuasive advertising man" (Giddens, 1973: p. 21) and the like, was obviously politically loaded. The entire information society thesis, according to a self-styled 'neo-Luddite' treatise, is a mere 'snow job' for the mercenary powers orchestrating the capitalist system (Webster and Robins, 1986: p. 31). This whole tradition of criticism was more recently epitomized in Scott Lash's aphorism that the information society is "an order in which the principle of 'society' becomes displaced by the principle of 'information'—that *society itself* has been lost" (2002: p. 75). Socialist intellectuals get understandably incensed when right-wing politicians cite the theory of postindustrialism as an excuse for closing mines and factories. And they are absolutely right to insist that the information economy is an inherently fragile affair, that at the end of the day information cooks nobody's dinner. There are elements of genuine substance in the radical critique of the information society thesis, but for its own part, the left must adjust its social analyses to accommodate new realities. An intelligent socialism will first interpret the world, before trying to change it.

Perhaps the most durable charge, finally, is technological determinism, a term that has become something of a bogeyman in social-scientific circles. The idea that technology has single-handedly caused the changes outlined above, the transformation of industrial, energy-driven societies into postindustrial, information-powered ones, is clearly untenable. Many more variables need to enter the equation if one is to grasp what is happening. On the other hand, to deny any causal efficacy to ICTs is to be unable fully to account for a veritable kaleidoscope of surprising events, not least the phenomenal rise of new social powers like Facebook and Google. While technology should not be deified or crudely reified, it should be credited with its own measure of agency, not just explained away as a social construction – and in practice no one really thinks otherwise. Political factors, economic factors, sociological factors, cultural factors, psychological factors, all obviously also play their part; but it cannot plausibly be claimed that seismic occurrences like, say, the Arab Spring or Edward Snowden's megaleak of US state secrets, would have materialized without digital networks and other benefits of the Information Age.

The Information Society Agenda Today

Notwithstanding whatever is valid in the critiques of the thesis, it is safe to say that the information society has in several nonnegligible senses arrived. Thus, one can conclude that its existential crisis is over. This is not at all to suggest a moratorium on empirical studies or social-theoretical analysis of the information society. These need to continue, now focused on probing the nature of informatization in its manifold national, regional, and global manifestations. However, the main research action of the future should be not the empirical but the normative, not the positive but the political (Duff, 2012; Dutton, 1999).

The information society agenda is vast and open ended, and only a few issues will be introduced below. However, a few generic points can be made about its logical structure. The information society agenda will probably not be articulated so much by crude dichotomies, like utopian *vs* dystopian or technologically determinist *vs* socially determinist; its mode will be the continuum, the synthesis. Temporally, the agenda will be increasingly oriented not only to the future but also to the past, to memory and tradition as well as innovation. Spatially, policies will be shaped by considerations of scale and 'granularity.' In addition, the character of information society policy is likely to be a function not only of advances in computer-telecommunications but also of extraneous technological systems, such as nuclear power. And its approach will of course be interdisciplinary, because complex social problems have no respect for artificial borders. Nevertheless, the information society agenda will be governed by the perennial preoccupations of political philosophy, as classically conceived in terms of values, such as freedom, social justice, and fellowship. Indeed, it could be argued that the overarching aim of information society forward thinking today lies in the development of nothing less than what Walter Lippmann (1989) called a 'public philosophy.' Finally, the setting of this agenda will be not only for policy elites and the academy, but for all who feel the impact of informatization – which is to say the entire citizenry.

Certain issues have been prominent. The digital divide, for example, enjoyed a remarkable vogue in the 1990s. The broader problem of information inequality had been festering for decades, but the arrival of the World Wide Web threw it into sharp relief (Norris, 2001). Vice-President Al Gore made access to the 'information superhighway' a front-page issue, championing a raft of socially inclusive initiatives, such as the retooling of schools and public libraries. Subsequent Republican administrations toned down the egalitarian rhetoric, perhaps sensing that this new focus on social divides was unwelcome to their patrons on Wall Street. In some ways, whether by public policy or the invisible hand of the market, the digital divide is lessening. For example, the Oxford Internet Institute (Dutton and Blank, 2011: pp. 8–9) estimates that the proportion of households and individuals using the Internet reached 73% of the British population in 2011. However, it is obviously still a major problem compounding other endemic inequalities within preindustrial and industrializing nations. And at a global level the imbalance of information flows and technologies between rich and poor nations was what prompted the World Summit on the Information Society, in many ways a resumption of an idealistic United Nations initiative of the 1970s, the New World Information and Communication Order (Vincent et al., 1999).

Moreover, it would be a mistake to deduce that the problem of inequality has disappeared entirely even inside the post-industrial world. We still have our own poor, and information poverty is a significant, and usually underestimated, dimension of their predicament. This goes far deeper than lack of technology ownership or access; indeed, postindustrial paupers seem sometimes curiously well equipped in gadgetry. The essence of their information poverty lies rather in their ignorance of 'normal' democratic information, those crucial

facts about legal rights, welfare and political representation that well-heeled citizens take for granted. It might be countered that they could access such data sets through public libraries, if not their own phones and televisions, but the deeper point is that they are in many cases too demoralized even to want to make the effort. And it is difficult to see how anything short of major structural reforms could alleviate such ingrained false consciousness. In short, if policy makers are serious about cracking information inequality they may need to consider putting social engineering back onto their agenda.

The rapid diffusion of ICTs – at far above the rate of most innovations (Rogers, 1986: p. 132) – has made another recurrent information problem much worse, that of content regulation. Here one might say that the agenda is now not so much 'information management' as 'damage limitation.' The incessant deluge of textual, photographic, audio, and video materials, much of it of dubious information-value and some of grave moral questionability, is posing as yet unmet challenges. The harsh reality is that children now look up anything they fancy and parents who try to stop them are like King Canute ordering back the waves. The technical architecture of the Internet defies hierarchical control – ironically, since it was originally set up by the US military establishment – so even when the authorities decide to act, they are typically frustrated by the ability of information to hide or relocate. The traditional tools of media regulation are useless, because cyberspace is not just a medium, or even a supermedium: it is the habitat of a whole new world, a world without end and one with its very own – to continue in a theological vein – demonic dimension. Scientific, technical, and medical information is far more widely available than ever before, but so are sadomasochism and suicide Web sites. Thus the challenge of the future will be to enable information liberation 'within the limits,' to borrow a phrase from Kant, 'of reason alone.'

Information security, a topic seemingly so arcane and dull, will also be at the top of the agenda. It is not very long ago that most people refused to reveal financial and personal information online; now citizenship is impossible without doing so all the time. Yet while security standards have improved, regular scandals about lost card details, leaked search logs, illegally accessed medical records, breached military firewalls, and so on, vindicate the slogan 'Information Wants to be Free.' Better systems will be made widely available, but perfect protection is an unattainable ideal, because the problem is behavioral and 'sociotechnical,' not merely technical. So we must ask not just how R & D can develop information security, but also how society as a whole can assimilate the intrinsic vulnerability of its central asset, information, and the gigantic risks that this entails.

The information society agenda may have to accommodate some explosive new issues. The population census, for example, is one of the oldest and most useful information institutions in the world, but its very familiarity has caused it to pass largely under the research and top-policy radar. That will need to change. Among the issues that the twenty-first century census must address are the following: Is a complete population poll still necessary, given recent advances in sampling and modeling? If the answer is affirmative, then is a purely online census – a highly likely scenario – compatible with the convivial ethos embedded in public practices such as censuses or voting? What further types of questions might a future census seek to ask of informants? And, if private information corporations are going to continue being hired to implement the census, should there be more stringent requirements? For example, the 2011 Scottish census's use of CACI (UK), whose parent company CACI International admitted supplying several interrogators at the notorious Abu Ghraib prison in Iraq, raised profound issues of conscience for citizens – some of who preferred fines or imprisonment to putative dirty hands. If, with the glacial 10-year interval that censuses afford, the authorities cannot get such decisions right, it bodes ill for the general prospects of ethical information policy.

All of these issues point to the central question of the State. Some theorists have not hesitated to write its obituary, as though this were integral to the information society thesis, yet they have so far marshalled little hard evidence. Others have sought with more success to identify a new species, such as the 'informational state,' which Sandra Braman in an important treatise (2006) sees replacing the bureaucratic welfare state. Yet others still strive to keep the focus on long-running fears about technocracy – technology-enabled dictatorship – and surely with good reason. *Nineteen Eighty-Four*, George Orwell's science-fiction homage to individual freedom, is often cited by the public at large. Scholars tend now to reference Jeremy Bentham's concept of the Panopticon, the hidden, all-seeing potentate, especially since it was given (post)modern, antiestablishment expression in the work of Michel Foucault. The sense that one might be being watched by unknown others, hence that one should be just a little more circumspect, is becoming almost definitive of contemporary human experience – both online and offline. The problem for the information society, then, is to work out how there can be effective limits to interference by the State, and not just by the State but by other social powers too, such as corporations, pressure groups, and paparazzi. Should we invent a new institution akin to religious retreats, mooted as far back as the 1960s (Kalven, 1997: p. 249)? An increasingly attractive thought, certainly, yet the main solution will surely not lie in quasi-monastic forms of life but in institutionalizing revitalized norms of privacy inside the quotidian world.

Finally, it perhaps makes sense to begin to speculate about what, if anything, might lie beyond the information society, assuming technocracy can somehow be averted. Some speak of 'knowledge society,' a concept developed with considerable skill by sociological thinkers, such as Nico Stehr (2008). At the opposite end of the cognitive scale, Klaus Jensen (1999) interestingly predicts a shift from information society to 'dream society,' a scenario in which stories and imagination displace the cold light of reason. And with most nations having seemingly already deserted the battle against mass unemployment, people should have plenty of time thus to dream. However, there is no need for a stark either/or. What is more likely is parallel and countervailing developments, a further informatization, scientification, and complexification of political society combined with increasing flights to realms of feeling, intuition, and metaphysics. Thus, the great technoprophet's paradoxical vision of a revival of felt religion, what he called "the great instauration" (Bell, 1996: pp. 146–171), could well come true.

Abstract

This article provides an overview of the sociospatial processes associated with the massive growth of information technologies over the past 20 years, as well as the intellectual developments that have sought to describe and analyze these processes. While geographers took on a key role in combating notions of the 'death of distance' in the 1990s, early research on the geography of the information society failed to create a coherent disciplinary approach. Recent work in geography has, however, created a more unified approach to understanding key sociospatial processes in the information society.

The 'information society' refers to the large-scale shift in contemporary societies where processes and practices of information production, analysis, and consumption take on an increasingly dominant role in social life. While the term typically refers to a broad array of information and communication technologies (ICTs), it has become most closely associated with the development of the Internet, the commercialization and popularization of which made the reality of an information society more visible and accessible to a wider range of people. Most recently, the spread of mobile phones throughout the developing world and the explosion of social media have made the previously new and exciting facets of the information society ever more routine through greater integration into the daily lives of people around the world.

The geography of the information society refers to the study of the new technologies and practices centered on information; the focus is on how these technologies and practices both are structured by longstanding sociospatial processes and act to reconstruct and reconfigure such processes. Given the centrality of the Internet in popular imaginations of the spatial expression of the information society, much of this research has focused on the so-called network of networks. Geographers have also been keenly interested in the growth of geographic information science and associated technologies over the past two decades, especially as Global Positioning System-enabled devices and spatially based search have become increasingly common in the past 5 years.

This article situates the concept of the information society in its historical and geographical context, while tracing the development of research on the geographies of the information society from their beginnings in the early 1990s to conceptual and methodological shifts that have taken place since the mid-2000s.

Situating the Information Society

Ultimately, any understanding of the 'information society' must begin from the context in which the concept emerged, which is intimately related to an understanding of what the information society is not, or at least what it is imagined not to be. While there is no single accepted definition of the information society or point at which society made a wholesale transition into the information society, the term is inextricable from the economic context of the 1970s, at which time deindustrialization and crisis were widespread in the developed Western economies (Bluestone and Harrison, 1982).

In response, many commentators pointed to the emergence of an economy, indeed an entire society, organized not around the production, exchange, and consumption of tangible, manufactured goods that were increasingly being produced more cheaply elsewhere, but of information (Touraine, 1971; Bell, 1973). Such ideas have continued to be influential, as more recent commentators such as Robert Reich (1992) and Richard Florida (2003) have argued that the future of Western economies rests on what they respectively refer to as 'symbolic analysts' or the 'creative class.'

The problem with such constructions of an 'information economy,' of course, is that they tend to neglect the fundamental interconnections between industrial and informational production, as well as the role of information in primary-extractive activities (e.g., the importance of information processing in petroleum exploration). Information has always been a crucial element of social and economic life, even in the industrial and preindustrial eras, just as material resources continue to be extracted and factories continue to manufacture goods in the supposed information age. After all, the computers, fiber-optic cables, server farms, and mobile devices that undergird today's information society have clear material presences and often significant environmental footprints as a result of their production, consumption, and disposal (Zook and Shelton, 2012).

So while computers, mobile phones, the Internet, and geographic information systems have all made significant impacts on social life in the last 20+ years, it is necessary to situate these technological developments within broader histories and understand that they exist along a continuum of quantitative intensification of information use, rather than as wholesale shifts or qualitatively different ways of living in and understanding the world. So while the information society as it is known is marked by real and important differences from previous areas, it is also deeply structured by the historical and geographical forces from which it emerged.

The Death of Distance?

The earliest commentaries on the geographies of the information society emphasized the new spatialities of economic activities related to globalization. Popular writing by non-geographers predicted that new ICTs would mean the 'death of distance' (Cairncross, 1997). Of course, such pronouncements were not without historical precedent, as similar claims were made of earlier advances such as the telephone, telegraph, and even of the postal service (Fischer, 1994).

Nonetheless, it was these popular, if fallacious, accounts that provided the impetus for a great deal of research on the geography of the information society, leading to a refutation of the claims of such popular writers. Rather than seeing these new technologies as having inexorable social effects, which in this case amounted to a spatial expression of technological determinism, geographers and other social scientists attempted to situate these new technologies in their social and spatial context, to understand them as contingent outcomes of particular processes with contingent effects. As Kirsch (1995) argues "space is not 'shrinking,' but rather must be perpetually recast" (p. 544).

But perhaps the earliest programmatic statement against such views of the space-transcending power of technology came from Manuel Castells' theorization of the network society, constituted by the divergent space of flows and space of places. Castells (1996) argued that the use of new communications technologies provided the means through which a new social organization could emerge, organized around the network logic of an electronic 'space of flows' overlaid on cities and localities. He argues that "[t]he space of flows is not placeless, although its structural logic is. It is based on an electronic network, but this network links up specific places, with well-defined social, cultural, physical, and functional characteristics …. Both nodes and hubs are hierarchically organized according to their relative weight in the network. But such a hierarchy may change depending upon the evolution of activities processed through the network" (p. 413). Thus, the 'space of flows' associated with the information society can enable a reformulation of place-based interactions into virtual interactions, but is merely a space of opportunity rather than a predetermined outcome. Instead, one sees the continued influence of places and their cultural and economic systems on the structure of the information society. Castells argues that these local factors, the longer standing 'space of places' in opposition to the newer 'space of flows,' determine the role of each place within the network and its importance or irrelevance.

While Castells' work promoted an interdisciplinary spatial perspective on the information society, early research on the geography of the information society tended to be somewhat diverse, with scholars addressing the Internet or associated technologies from a particular disciplinary or theoretical standpoint (Hepworth, 1990; Kellerman, 1993). For instance, while some political geographers studying the Internet might focus on the way social movements incorporated the Internet into organizing or protest strategies, economic geographers were investigating how the Internet was integrated into existing networks of production. Although the influence of such disciplinary divisions made it difficult for geographers to produce a unified body of theoretical and empirical work around the information society, and thus promote a lasting institutional home for this research, it is important to review and understand this work in this context.

Geographies of Urban and Economic Restructuring in the Information Age

Just as the definition of the information society itself tended to revolve around ideas of economic restructuring, so too did the earliest and perhaps most prominent work by geographers on the topic. Although geographers were always quick to point to the lack of nuance in arguments about the end of geography, even the earliest works touching on the geographic implications of new ICT offered ideas such as 'time–space compression' (Harvey, 1989) that highlight the connection between new technologies and globalization.

But further developments have tended instead to emphasize the simultaneous concentration and dispersal of economic activity. That is, while ICTs undoubtedly have allowed for economic transactions to take place over much greater distances, this process has been accompanied by a concurrent concentration of certain activities in particular places. So rather than seeing urban dispersal and dissolution as the result of these new technologies, urban and economic geographers have argued that cities continue to be crucial players in the information society.

On the one hand, the prototypical industries of the information economy have remained largely clustered in a handful of locations that specialize in knowledge production and innovation. Places like Silicon Valley in California, Route 128 in Massachusetts, the Research Triangle in North Carolina, as well as Cambridge in the United Kingdom and Tokyo in Japan, remain home to some of the world's most important electronics and biomedical companies. Instead of representing the death of distance, these clusters testify to the enduring relevance of agglomeration economies. Similarly, it is clear that economic activity in the information society tends to cluster in cities. Rather than exhibiting a placeless character, the infrastructure of the Internet, has emerged from long-standing political and economic processes, meaning that prominent 'global cities' such as New York and London have not been threatened by the Internet, but in many ways have been made even more important (Malecki, 2002). In addition, the information processing industry as a whole, including both those specializing in the development of the technologies themselves and those specializing in producing informational content, also remained highly clustered in a few cities, although in this respect cities like San Francisco were able to gain a relative advantage, solidifying their importance to the global system to which they had previously been peripheral (Townsend, 2001; Zook, 2005).

But the geographic contours of urban and economic restructuring in the information society are not limited simply to the positionality of major cities in the global economy. Indeed, the growth of the information economy affects the internal spatial structure of cities as well, ranging from growth in traffic congestion to changing roles for various

neighborhoods in the aforementioned cities. For instance, Graham (2002) documents how the dot-com boom in San Francisco led to a pattern of 'cyber gentrification' in some neighborhoods, marginalizing poor and minority populations in order to make way for wealthy tech start-ups. Areas zoned for light industry saw the influx of mixed-use loft developments that met the letter of the law while greatly increasing real estate costs, thus forcing manufacturing firms to close or relocate. So while the new activities and capabilities of the information society have enabled the restructuring of economies and city-regions, these new processes demonstrate the persistently variegated and multiscalar processes of uneven geographical development typical of earlier iterations of capitalism.

Globalizing Identities and Protest Movements

Just as urban and economic geographies have brought their own conceptual frameworks to the study of the information society, so too have a number of cultural and political geographers, although their numbers have been considerably smaller and somewhat less prominent. The most common thread woven through political geographies of the Internet have focused on the potential of the Internet to reconfigure the spatial relations of protest, allowing oppositional social movements to 'scale up' and reach broader audiences, which might in turn be able to promote their cause (Adams, 1996). And while there has always been significant skepticism about the ability of the Internet to enact change independent of broader social structures, the Internet continues to be seen as a key tool for social movements in that it offered a relatively unregulated space where oppositional and counterhegemonic discourses could flourish (Warf and Grimes, 1997; Froehling, 1997).

Similarly, cultural geographers have seen the Internet as an important contributor to the formulation and maintenance of identity. In some cases, the Internet has allowed diasporic groups to maintain a level of social cohesion despite the lack of colocation (Adams and Ghose, 2003), while in other examples the Internet has allowed identity to become more fluid in virtual space, perhaps even becoming divorced from corporeality (Roberts and Parks, 1999). Although cultural and political geography approaches to new technologies have become increasingly prominent in recent years, as will be described in the following section, these subdisciplinary perspectives were largely peripheral to debates going on elsewhere in the discipline and in studies of the information society more generally.

Toward New Geographies of the Information Society

While earlier approaches to Internet geographies were largely approached from preexisting subdisciplinary perspectives, with the Internet as a common object of analysis, theoretical and methodological shifts, along with technical developments and ever-expanding access to these technologies, have led most recently to efforts to create a more integrated approach to understanding the geography of the information society, with a series of central themes or problematics. While much work remains to be done, the authors identify four interrelated themes that have emerged within the past decade, and which promise to extend this line of research into the future.

Hybrid Spaces and the Virtual/Material Binary

The first and most important of these themes is the issue of the relationship between virtual and material spaces. Perhaps the most important contribution to this literature has been the conception of space as hybridized, or as variegated mixture of both material and virtual, rather than a so-called real world and an ontologically distinct cyberspace that we can choose to integrate into or remove ourselves from (Graham, 2013; see also Aoyama and Sheppard, 2003). As such, it becomes more and more difficult to conceive of the Internet as an analytically distinct object of analysis, leading one to conceive of practices, processes, and geographies of information as a unified set of phenomena worthy of study. Instead, one should understand "These cyberplaces are not simple floating and static mirrors of the physical world. They are instead often a component of the palimpsest of place. The virtual Earth and digital representations of place are often characterized by a reflexive relationship with their physical counterparts: they are shaped by, and, in turn, shape the physical world" (Graham, 2010: p. 423).

This unity includes everything from how one's movements through urban space are controlled in part by information profiles about him or her as individuals and types (e.g., radio frequency identification tags, biometric scanning, and pattern recognition), to the ways in which one's interpretation of cultural landscapes are shaped and influenced by increasingly available information and commentary about places that can be engaged with *in situ* and in real time. In short, the growing importance of computation to social life, beginning in the 1950s with the processing of government and insurance records, has become so deeply integrated into everyday life that the idea of 'the information society' is somewhat passé. Therefore, one might say that the geography of the information society is the geography of society writ large.

Rethinking Places and Flows

In addition to an understanding of space as hybridized has been a rethinking of the binary logics that underpinned earlier theorization about flows vs places, or of spatial distanciation vs localization. As was mentioned previously, many of the necessary correctives to death of distance thinking still involved an understanding of social relations stretched over wider and wider geographic areas.

In contrast, the last 5–10 years of work on the geographies of information have increasingly focused on how ICTs do not simply lead to a stretching of social relations but in many cases are implicated in the production of more intensely localized social relations, allowing for a closer connection to one's own place as much as, if not more than, allowing one to connect to someone half a world away.

This awareness of the place-based character of ICTs necessitates a rethinking of the classic Castellian binary between places and flows. It is necessary to understand, following the idea of hybrid spaces, that spatial relations are simultaneously

place based and flow based. For instance, the effects of ICTs on economic processes are no longer seen to allow simply for the outsourcing of production facilities or back-office functions around the world. Instead, it is clear that flows of material goods around the planet – a phenomenon in no way limited to the last 30 years of globalization – are fundamentally supported by accompanying flows of virtual information. As commodities are produced and consumed, the global economy is increasingly dependent on information produced about and attached to these commodities in order to connect them to their places of origin, their conditions of production, and their final resting place in the form of waste (Zook and Shelton, 2012). So just as one has been able to move past binaries between the virtual and the material, so too is it necessary that one moves past binaries between the local and the global, or between spaces of places and spaces of flows.

Code/Space

Another important theme in recent writing on the geographies of the information society has focused on the role of software in the remaking of social and spatial processes. Software code embedded in buildings, roads, traffic signals, and automobiles, among other things, acts as a constraint on the range of possible choices, allowing particular spaces to be used only in particular ways while simultaneously enabling certain forms of action. For instance, the failure of software-mediated processes can quickly repurpose a grocery store into a massive warehouse when check-out scanners no longer work or an airport into a simple waiting room when electronic tickets become inaccessible. Similarly, the code embedded in computers, mobile phones, and various search engines and social media applications structures one's ways of seeing the world by automatically sorting the massive amounts of information available to provide one with simplified and algorithmically constructed view of the built environment through which he or she moves (Zook and Graham, 2007).

Kitchin and Dodge (2011) understand the role of software code as a process of simultaneous translation and transduction. While the production of software code entails the inscription of certain commands, values, and social structures into automatically enacted instructions, the use of this code in turn produces new effects in the world, altering the ways that new iterations of code will structure one's experiences in the world. But, as Thrift and French (2002) lament, the incredible power of software in the world has not been subjected to the same critical scrutiny as other similarly powerful technologies. They argue that attention to the spatialities of software has been limited because we are trained not to see it, to ignore its presence in the interstices of our lives and social processes due to its absence from our field of vision. While this research remains relatively new, it is promising insofar as geographers have been at the forefront of such studies, integrating an explicitly spatial perspective into the interdisciplinary field of software studies.

Volunteered Geographic Information and Big Data

But the importance of such information does not come only from being produced and implemented from the top-down. For another key element of the information society has been the shift in who is producing the information at the heart of our society. Increasingly, such information is being produced by amateurs rather than professionals and shared openly through a variety of online platforms, or what has been described as the shift from Web 1.0 to Web 2.0. And as that information is increasingly tied to particular places through the practice of geotagging, it opens up new opportunities for citizens to produce their own digital representations of place through what is known as 'volunteered geographic information' (Goodchild, 2007). This layer of virtual information is a key element in the production of hybrid landscapes – blurring the boundaries of the virtual and material – in which the understandings of the material world are influenced by representations in the virtual world, which in turn influence how one lives in and reproduces those same spaces. While Graham and Zook (2011) outline a methodology for understanding these layers of place-based information and interrogating the ways they do and do not reflect sociospatial processes offline, these methods have similarly been applied to understand topics as diverse as disaster response (Crutcher and Zook, 2009) and religious landscapes (Shelton et al., 2012).

When collected, aggregated, and cross-referenced with other large databases of information, this user-generated content becomes one part of a mass of so-called big data, providing potentially unprecedented insights into social interactions. While big data offers researchers a rich source of contextual data from which to work, equally interesting work has emerged on the social conditions giving rise to the phenomenon of big data and how it is shaping academic research and modes of thinking, as well as the way we as citizens and consumers relate to the public and private sector institutions we are dependent upon (cf Crampton et al., 2013). And while big data remains a nascent and contested idea with a variety of possible futures, it has the potential to reconfigure social and spatial relations in new and interesting ways, just as other rounds of technological innovation in the information society have done.

Information Structure in Linguistics

Abstract

Information structure is a subfield of linguistic research dealing with the ways speakers encode instructions to the hearer on how to process the message relative to their temporary mental states. To this end, sentences are segmented into parts conveying known and yet-unknown information, usually labeled 'topic' and 'focus.' Many languages have developed specialized grammatical and lexical means of indicating this segmentation.

Theoretical Background

The term *information structure* refers to the ways linguistically encoded information is presented relative to the speaker's estimate of the temporary mental state of the receiver of the message (cf Chafe, 1976). Utterances transmit both the information contained in the message and the implicit or explicit instructions on how this information is to be processed and integrated into the hearer's knowledge stock. In order to achieve this, the speaker has to decide which parts of the sentence are 'old' or 'given' and which are 'new' for the hearer. The hearer is led to identify those elements of her existing knowledge ('given elements') which shall be relevant for the processing of the message. The information comes about by relating the 'new' elements (i.e., what the hearer is assumed not to be aware of) to these 'given' elements. The speaker's choice of 'given' and 'new' segments within a sentence depends on her hypotheses about the current state of the hearer's attention and consciousness. Information structure thus relates two major functions of language, as a means to transmit knowledge and as a vehicle of social interaction. Linguistic research on information structure is based on the assumption that natural languages are equipped with formal means of signaling the basic distinction between known and unknown pieces of information, and a number of other distinctions. This research draws from a rich philosophical and psychological tradition and has been established as a separate field of linguistics in the past 50 years.

The way information structure is rendered overt in natural languages is illustrated in the sentence pairs (1)–(2) (small capitals mark the position of the sentence stress).

(1a) Jonathan opened the DOOR. (English)
(1b) JONATHAN opened the door.
(2a) Peter hat gestern das FAHRRAD genommen. (German)
P. has yesterday the bicycle taken
'Peter took the BICYCLE yesterday.'
(2b) Das Fahrrad hat gestern PETER genommen.
the bicycle has yesterday P. taken
"As for the bicycle, PETER took it yesterday."

In (1a) and (1b), the sentence stress indicates what the hearer is to treat as new elements, the locus of information update. This is clearly apparent if one observes different context compatibilities of (1a) and (1b): the former is a felicitous answer to the question "What did Jonathan open?", while the latter answers the question "Who opened the door?". The carrier of sentence stress in English thus seems to indicate what element(s) of the clause carry the desired information update, as it is this part of the sentence that is regularly used to fill the gap in the hearer's knowledge marked by the question word. This kind of element, which brings about information update, is usually called *focus*. Sentences (2a) and (2b) illustrate how 'given' elements work. In German, given elements are usually marked by the clause-initial position. The normal use of these sentences in context reveals the differences in their information structure: while (2a) is fine in a situation in which the interlocutors are talking about Peter and his mischiefs, (2b) would be used if the conversation is about the whereabouts of the bicycle. In the former case, 'Peter' is the segment of the message toward which the attention of the interlocutors is directed; in the latter, this segment is 'the bicycle.' Given elements to which the hearer is expected to relate the information update are called *topic*. Importantly, both examples (1) and (2) show that the information conveyed by the message is intended to increase the hearer's knowledge about the topic by ascribing the denotation of the focus to this topic. In (2b), for instance, the speaker intends to inform the hearer about the bicycle (topic), and does so by ascribing it the property of being taken away by Peter (focus).

This idea of information structure is rooted in a particular model of communication, the incremental model (Stalnaker, 1999). According to this model, communication consists of reducing the differences in the knowledge of the interlocutors by increasing the *common ground* between them, i.e., their stock of shared knowledge. In order to do this, constraints on the input to the common ground have to be taken into account: only such content can be added which relates to the previously existing knowledge. Since the particular portion of the existing knowledge relevant at the current point in communication is not necessarily manifest per se, it often needs to be indicated linguistically, via *presuppositions*. The content that is added, the proposed change in the output common ground, is related to presuppositions via *assertion*. Similarly, other speech acts have effects on common ground, so that, for instance, questions identify which type of content is expected to be added to which presupposed portion of knowledge. By structuring the transmitted information, speakers indicate how this

permanent change of common ground should develop, so that information structure itself has been occasionally defined as a *common ground management* system (Krifka, 2008). Information structure research assumes that this common ground management system operates via a number of linguistic categories. These minimally include topic and focus, but some approaches differentiate no less than half a dozen of categories (see the 'Categories of Information Structure' section).

Categories of Information Structure

Topic (also called *theme*, *link*, *given information*, etc.) has been defined in a number of ways, depending on the general model of information structure. Two major competing definitions are those based on the notions of *givenness* and *aboutness*. Givenness-based definitions are hearer-centered: topic is that part of the utterance that is assumed to be already known to the hearer, present in the common ground of the interlocutors, and/or activated in the hearer's short-term memory, by being mentioned previously, inferable, or given in the extralinguistic context. The alternative view is that topic is that part of the utterance about which this utterance is meant to give information. The focus is here more on the speaker's intentions than on the hearer's state of mind: the speaker determines what she intends to increase the hearer's knowledge about and encodes this element as a topic. As shown by Reinhart (1981), the aboutness-based definition is empirically superior, even though the notion of givenness cannot be fully excluded from definitions of topicality. Speakers seem to be free to choose what segments of the hearer's knowledge they intend to enrich with new content, so as to increase the common ground. However, they are constrained by the considerations of the hearer's processing capabilities. What is chosen to be a topic of a given utterance is generally in one way or another given/old and thus easily accessible to the hearer; otherwise, the hearer is confronted with the double task of identifying inaccessible, inactive knowledge and adding new content to that segment of their knowledge. This usually leads to a breakdown of communication, or at least to infelicitous utterances, as seen in examples in (3).

Context: Why didn't you come to work yesterday?

(3a) I have some elephants I take care of. Yesterday, one little elephant was ill.
(3b) #Yesterday, one little elephant was ill.

The second clause in (3a) is felicitous, since its topic, 'one little elephant,' has been indirectly introduced previously and thus made accessible to the hearer. The answer in (3b) is communicatively bad, since it forces the hearer to accommodate a rather unusual piece of knowledge (the speaker takes care of elephants) and to ascribe it a property of being ill at the same time. Topics are thus elements of the proposition that the utterance is construed about, and that are usually restricted to given, accessible elements.

Focus has been defined in even more different ways, and has been labeled even more variably; other, partly or mostly synonymous labels include *comment*, *rheme*, *new information*, etc. Intuitively, focus is the locus of the common ground update, the element that carries the proffered new content. The two most prominent theoretical approaches to focus are Alternative Semantics and the assertion-based theory of focus; other approaches include Givenness Theory, Structured Meanings Theory, etc. (see Krifka, 2008 for an overview). The assertion-based approach to focus (Lambrecht, 1994) defines focus as that part of the proposition by which assertion differs from presupposition. Importantly, focus is not equated with assertion, as assertion, i.e., update, comes about only by applying the new content to the presupposed content. Focus is rather defined negatively, as the segment that is not presupposed. This definition relies heavily on the incremental model of communication and treats focus as a propositional phenomenon. Alternative Semantics (Rooth, 1992) attempts to develop a denotational semantics for focus, treating it as an operator which generates alternatives to the expression that is focused. Informally, focus indicates alternatives relevant for the interpretation of the focused expression. In processing a focused element, the hearer must assume that this element can be interpreted only with respect to some set of alternative denotations. This is illustrated in (4) and (5).

(4) Who broke the vase? $[\textsc{Peter}]_{focus}$ broke it.
(5) They were quarreling about buying a present. In the end, $[\textsc{Mary}]_{focus}$ bought it.

The question in (4) indicates that there are a number of possible culprits for the destruction of the vase; the focus of the answer, 'Peter,' picks out one of these referents and, by evoking alternative values (e.g., 'John,' 'Mary,' etc.), relates it to the set induced by the question. The same mechanism is at work in (5): the focus on 'Mary' indicates that there were other potential present-buyers.

The assertion-based approach and Alternative Semantics are not mutually exclusive. As shown by Matić and Wedgwood (2013), alternatives necessarily arise whenever something is newsworthy enough to be asserted. Assertion is, as it were, plausible only when things could have been otherwise. However, some important differences remain: while assertion-based theories allow for focusing only at the level of propositions, nothing in Alternative Semantics prevents smaller linguistic entities, such as noun phrases, from having information structure of their own. The two major approaches to focus thus differ in the assumed scope of information structure. Some researchers, mostly those that assume some version of Alternative Semantics, take information structure to be recursive, so that not only the sentence is segmented into topic and focus, but also its component parts (e.g., Rooth, 1992). Others restrict information structure to propositional entities, since only propositions can have truth values and contribute to the update of the common ground (e.g., Lambrecht, 1994). The issue is not fully resolved, and it is sometimes conflated with yet another unresolved aspect of information structure research, that of the number of its dimensions. Researchers differ with respect to the number and kinds of subdivisions and categories involved in informational segmentation of the utterance. The minimal assumption is that all sentences fall into two parts, the topical and the focal one. In some approaches, it is assumed that in addition to topic and focus, there is a transitional informational element that indicates how new content (focus) is to be related to the topic (*transition*

in Firbas, 1992; *tail* in Vallduví and Engdahl, 1996). Other approaches take it that different dimensions of information structure are realized in different structural domains. It is thus often claimed, with different terminologies, that there are two different levels: the topic–comment and the focus-background articulation, which are orthogonal to one another (e.g., Halliday, 1967; Vallduví and Vilkuna, 1998; Kruijff-Korbayová and Steedman, 2003). The topic–comment division corresponds roughly to what assertion-based theories of focus describe as information structure, bringing new content (comment) into relationship with a piece of the existing knowledge (topic), while the focus background partition expresses the existence of alternatives for focus and the lack thereof for background. The former is a sentence-level phenomenon, whereas the latter is recursive. The way these various divisions function is illustrated by example (6), adapted from Kruijff-Korbayová and Steedman (2003).

6. Q: I know that this car is a Porsche. But what is the make of your other car?
   A: (My OTHER car) (is ALSO a Porsche)
   (Background Focus) (Background Focus Background)
   Topic **Comment**

In other systems, what is labeled as topic and comment in (6) would be called topic and focus, and no other subdivisions would be acknowledged; or the comment in (6) would be subdivided into focus ('also') and transition, or tail ('is a Porsche').

Apart from these basic categories, subdivisions, and dimensions, a number of other categories are occasionally mentioned. The most persistently discussed one is *contrast* (Repp, 2010). It is occasionally equated with focus, especially in the form given to the latter in Alternative Semantics (Rooth, 1992); or it is assumed that it is a separate category of information structure, compatible with both topics and foci (Vallduví and Vilkuna, 1998; Molnár, 2002). There are opposing views, too: ever since Bolinger (1961) it has often been argued that contrast is merely a matter of pragmatic inference, not a separate linguistic entity (Zimmermann, 2008).

Research Traditions

The roots of information structure research reach deep into antiquity (good historical overviews are provided by Seuren, 1998; von Heusinger, 1999). The basic concept of the division of sentences into two parts, subject and predicate, goes back to Aristotle, who used it somewhat ambiguously to refer to the dichotomy of judgment at the logical, psychological, and grammatical levels. The rise of linguistics and modern logic in the nineteenth century brought the revival of the subject–predicate discussion. Linguists like Georg von der Gabelentz and Hermann Paul developed a theory of *psychological subject* and *psychological predicate*, applying the traditional Aristotelian dichotomy to the temporary psychological states of the interlocutors. They were also the first to notice the interconnectedness of information structure and discourse context, as shown by Paul's use of the question–answer test (see the analysis of example (1)) to show different configurations of subject and predicate. The growth of Gestalt psychology at the turn of the centuries, with its insistence on the perceptual dichotomy between *figure* and *ground*, triggered further interest in information structure. The idea that human subjects are capable of understanding foregrounded objects only by relating them to their background naturally relates to the theory of psychological subjects and predicates. The decisive move from psychology to linguistics was undertaken by the linguists of the Prague School, especially Vilém Mathesius, who used the categories derived from psychology and philosophy to account for phenomena of word order variation and prosody. The subject–predicate division was replaced by that of theme and rheme (later topic and comment, or topic and focus). The Praguean ideas of information structure were disseminated in the wider linguistic community through the work of Halliday (1967–68), who modified and refined the notion of theme–rheme partition. On his view, information structure (the term was coined by Halliday) is a component of grammar separate from syntax and semantics, but it interacts with both in a number of complex ways.

From the early 1970s, information structure has become an integral part of many grammatical theories and a frequent research topic in descriptive linguistics. Chafe (1976) has developed a framework in which many of the notions discussed above have been systematized for the first time. His work has spawned a number of approaches which share the view that information structure needs to be linked to the communicative and psychological reality of language users, no matter whether it is considered a proper part of grammar or a communicative, pragmatic phenomenon influencing grammar (e.g., Vallduví, 1992; Lambrecht, 1994; Van Valin, 2005). Important developments in this line of research are Vallduví's (1992) application of file change semantics to information-structural phenomena, where knowledge is conceived of as a set of file cards which get activated and deactivated, and Lambrecht's (1994) explicit embedding of information structure in the Stalnakerian model of communication. Another line of research was conceived in the generative framework, most notably by Jackendoff (1972). The principal purpose is to find a way how categories like topic and focus can be represented in grammatical description so as to account for the range of grammatical structures influenced or triggered by information structure in a maximally economical way. A device that has been used almost universally to achieve this aim is the representation of information-structural categories as grammatical features (F-feature for focus was introduced by Jackendoff himself) which trigger word order permutations and determine sentence stress assignment and similar phenomena. Further developments include the postulation of dedicated hierarchical positions for topic and focus (Rizzi, 1997) and optimality-theoretical accounts of the interaction of the focus feature with sentence structure (Büring, 2006). In recent years, important attempts have been made to formalize the relationship between discourse structure and information structure (Roberts, 2012). The basic idea is that the discourse develops through a series of implicit questions under discussion. The information structure relates the utterances to these underlying questions and thus renders the discourse structure transparent.

Information Structure in Grammar

The linguistic interest in the phenomena of information structure stems from the fact that many formal features of language, such as prosody or word order, are intimately connected with information-structural variation. It is thus generally agreed that the assignment of sentence stress in many languages is determined by the position of focus (Ladd, 2006), as illustrated in examples (1a, b). Word order is also affected by information structure in many languages, either via optional rearrangement of constituents, as in German examples (2a, b), or via obligatory movement of information-structurally marked constituents to certain positions in the clause, as in Hungarian, where focus has to be immediately preverbal (compare the neutral sentence (7a) with the focus sentences in (7b) and (7c)). Other expressive means are also attested. Syntactic transformations of different kinds are found in most languages of the world; the best known example is cleft sentences, which in some languages, such as French, play a major role in signaling information structure (8). Many languages of the world have specialized morphology to indicate topic, focus, or some kind of contrast; the Japanese particle *wa* is a well-known example of a topic morpheme (9), while the case marker *–ləŋ* and the agreement suffix *–mələ* in Yukaghir (isolated language spoken in northern Siberia) is an instance of focus-indicating morphology (10).

(7a) János meg-ette az almát. (Hungarian)
J. PERFECTIVE-ate the apple.
"János ate the apple."

(7b) János ette meg az almát.
J. ate PERFECTIVE the apple
"JÁNOS ate the apple."

(7c) János az almát ette meg.
J. the apple ate PERFECTIVE
"János ate the APPLE."

(8) C'est maman qui décide. vs. Maman décide. (French)
it's mother who decides mother decides
"It's MOTHER that decides." vs. 'Mother DECIDES.'

(9) Inu wa hasitte iru.
dog TOP running is
"The dog is RUNNING." (Japanese)

(10) Taŋ köde metin čoγojə-ləŋ tadi-mələ
that man to.me knife-FOC give-OBJECT.FOC.3SG
"that man gave me a KNIFE." (Yukaghir)

It is unclear whether it is possible to establish cross-linguistic regularities which would subsume all these different types of structures. Attempts to establish one universal information-structure-based sentence template out of which variable systems could be derived have not been successful (see Matić and Wedgwood, 2013 for a critique). Recently, there have been noteworthy attempts to reduce the number of possible information-structure types to a limited number (Van Valin, 1999) and to derive the cross-linguistic variability from some more fundamental processing strategies (Büring, 2010), but all these attempts need further elaboration. Irrespective of this, it has been shown that, in one way or another, information structure does play an important role not only in such patent cases as word order variation or prosody, but also in reference resolution, long-distance dependencies, extraction, etc. (Van Valin, 2005, Erteschik-Shir, 2007).

The question of regularities that govern the form of information-structure-related structures in the languages of the world is not the only debated issue. The position of information structure in grammar is also a matter of dispute. The dispute revolves around two interconnected topics. First, is the proper domain of information structure semantics or pragmatics? Second, how is it connected to grammar? The answer to both questions depends on the definition of the semantics/pragmatics distinction one adopts. On one view, semantics is only what is truth-conditionally relevant. In most cases, topic and focus have no truth-conditional relevance whatsoever, so that they can be considered a proper subdomain of pragmatics. However, in some cases, they do seem to trigger truth-conditional effects, as in some kinds of generics and in certain types of conditionals. The best known examples include focus-sensitive expressions, whose interpretation seems to fully depend on focus assignment, so that they are considered *associated with focus* (Beaver and Clark, 2008). Such expressions are, among others, many particles, such as *only*, *also*, *even*, etc. The truth-conditional impact of their association with different foci is illustrated in (11).

(11a) John only likes BANANAS (and nothing else).
(11b) John only LIKES bananas (and has no other relationship to them).
(11c) Only JOHN likes bananas (and nobody else).

This property of information-structural categories has often been adduced as a proof of their semantic nature (e.g., Rooth, 1992). However, one might argue that the differences observed in (11) are a mere product of pragmatic inference arising out of the meaning of the particles in particular contexts. The issue needs further research.

A different idea of the semantics/pragmatics distinction is based on what is linguistically encoded vs what needs to be derived inferentially. From this point of view, the question is whether the structures identified as connected with topic, focus, etc., are indeed dedicated to expressing the meanings of topic, focus, etc., or whether these meanings are rather pragmatic effects derived from quite different denotations. The answer to this question is an empirical one: each information-structurally marked construction in a language needs to be tested for its primary denotation, and, if it turns out that this structure is not primarily an information-structural category, a pragmatic mechanism needs to be defined through which information-structural effects come about. Some first results largely diverge: Beaver and Clark (2008) convincingly argue for focus as the encoded meaning of the sentence stress in English, while Matić and Wedgwood (2013) show that many apparent focus-denoting structures, such as English clefts or Somali focus morphology, can be better analyzed as having distinct (identificational, modal, aspectual, etc.) denotations with interestingly similar information-structural effects. It thus seems that information structure can but need not be an element of grammar, depending on whether the given language has grammaticalized the categories of topic, focus,

etc., or not. Information structure is thus a universal phenomenon of human communication, but it is not necessarily a universal phenomenon in natural language.

Abstract

This article assesses the current status of the economics of information. The focus is on the acquisition of information (search) and the incentives associated with asymmetric information (noncooperative game theory). The evolution of these two areas also is presented along with simple examples. Their evolutions have a similar structure. The formal, abstract development of search is separate from its informal, concrete growth. At critical points the two paths intersect. The unification and illumination generated by these sudden meetings propel the economics of search to higher levels of understanding. In the economics of asymmetric information, game theory comprises the formal trajectory and industrial organization, broadly construed, is the relatively informal path. Econometric methods, devised shortly after an intersection, have exploited the empirical aspects of the new search paradigm. Experimental economics is performing an analogous function in the economics of asymmetric information. The article concludes with predictions regarding future developments.

Introduction

Prior to the 1980s, the 'economics of information' usually meant the economics of search. Search began in the 1960s with the seminal research by George Stigler, which spawned an enormous and growing literature. Both search and noncooperative game theory are considered in this article. As we will see, they are closely related and much can be gained by fostering a closer relation.

Stigler modified competitive price theory by noting that price is a random variable with a given cumulative distribution function. He thereby enlarged price theory to include the search activity necessary to gather information about prices. He defined search as follows: "A buyer (or seller) who wishes to ascertain the most favorable price must canvas various sellers (or buyers) – a phenomenon I shall term 'search'." The author of the famous text *The Theory of Price* knew that search theory would receive widespread attention because of its intimate link with price. That is, the primary reason for the almost immediate influence of Stigler's work was his focus on price uncertainty. Any such major change in price theory eventually would reverberate throughout all of economics. This is what has occurred since the 1960s.

The game theory meaning of the 'economics of information' centers around the formation, continuation, and dissolution of contractual relationships. The incentives of parties to a contract are determined by the different information possessed by each. To exemplify these asymmetric information problems, consider an auction of a valuable object with the following information structure. There are two buyers and one seller. One buyer is willing to pay more for the object, while the other has more information about the object's relative price. If the buyers can collude, "the Nash program directs us to view this collusion as the outcome of a process of communication where each player has choices about what to say. In this process, the more-informed buyer may try to mislead the less-informed buyer about the value of the object, and the less-informed buyer should rationally take this possibility into account" (Myerson, 1999: p. 1075). All problems of incentive-based 'economics of information' can be formulated as Nash noncooperative games.

While Stigler's information model fits snugly into standard price theory, Nash's noncooperative game theory complements price theory, but is not reducible to it. Stigler's fit is snug because he takes the distribution of prices as exogenously determined. This corresponds to the basic assumption of price theory – consumers accept prices as exogenous. Thus, the equilibrium problem is not addressed. Nash enlarged the scope of price theory so interactive behavior can be studied in almost any social institution. This was apparent only after the contributions by Harsanyi, Selten, Kreps et al., thereby explaining the long period between Nash's discovery and its adoption by the economics profession.

In recent years these two research programs have started to merge. Search is embedded in Abraham Wald's sequential analysis in that it determines when the process of information collection should terminate. Gideon Schwarz (1994) notes that Wald used the theory of two-person zero-sum games to unify statistical inference. Statistical inference was viewed as a game played by the statistician against nature. Statistics from this game theory perspective was called decision theory. One of the most important topics in decision theory is optimal stopping. Thus, game theory is as applicable to search as it is to other informational problems in economics.

Search Theory

Introduction

Modern search theory solves the problem of when to terminate the collection of information and take an action. Search is the confluence of two seemingly unrelated intellectual streams: the formal evolution of optimal stopping rules beginning with Cayley (1875) and the verbal, common sense literature found in Knight (1921) and implicit in Adam Smith. The first stage of this confluence occurred when Stigler (1961) blended these two streams with his fixed-sized-sampling rule. The second stage replaced the fixed-sized sampling rule with an optimal stopping rule, thereby combining the insights of Stigler, Bellman, and Wald.

The third stage seeks the source of an endogenous distribution of prices (wages) to replace the exogenous distribution in the Stigler and sequential models. This large and complex research effort was initiated by Rothschild (1973). The fourth stage replaced the one-sided sequential model with a two-sided

 http://dx.doi.org/10.1016/B978-0-08-097086-8.71042-7

equilibrium problem, where there is competition and interaction among optimizing agents. This ongoing research is based on the matching and bargaining models devised by Diamond, Jovanovic, Maskin, Mortensen, and Pissarides.

In the early work on search, many economists placed a much higher value on the verbal insights of common sense, when they sought a solution to a search perplex. Mathematical formulations of these insights were undervalued. Today, the situation is somewhat reversed in that formal analysis is applauded, while common sense is depreciated. Both attitudes diminish economics. The first does not encapsulate insights in a formal model. Hence, testing and extensions are difficult if not impossible. The second closes off economics from the imaginative intuitions of common sense.

Intuitive, Common Sense Precursors to the Economics of Search

See Lippman and McCall (1993) for further detail.

In 1930, Cannan clearly saw the *moral hazard* problem associated with unemployment insurance. He also noted that the best strategy for a job-seeker was to "Take what you can get now or hold out another week, when something better may turn up." With the advantage of hindsight this looks very much like the reservation wage policy.

In 1932, Hicks recognized the unanticipated unemployment effects of the search which is connected to the presence of imperfect information, when he claims that firms' "knowledge of opportunities is imperfect [whence] it is not surprising that an interval of time elapses between dismissal and reengagement during which the workman is unemployed." His statement that "the unemployment of the man who gives up his job in order to look for a better one" recognizes that voluntary unemployment is joined with search as a productive activity.

An early explicit statement viewing search unemployment as a productive activity was made by Hutt in 1939.

> A worker … may refuse immediately available work…because he feels that to accept it will prevent him from seeking for better openings. …. When actively searching for work … he is really investing in himself …. He is doing what he would pay an efficient employment agency to do – the search for a better opening is worth the risk of immediately foregone income.
>
> Hutt 1977: p. 83

In addition to the labor literature anticipating the job search model, other prominent precursors in the economics of search include Knight, Schumpeter, and Alchian who were concerned with the search for natural resources, the search for inventions, and evolutionary economics. Knight (1921) was keenly aware of the ancient activity of prospecting for natural resources "where the possibility of securing wealth by the discovery of natural resources is known … resources will be attracted into the field of searching for them in accordance with men's estimates of the chances of success in relation to the outlays to be incurred."

Schumpeter (1942) continued the advance toward Stigler's introduction of search in his concern for uncertainty and the opportunistic contractual behavior which uncertainty fosters.

> Practically any investment entails, as a necessary complement of entrepreneurial action, certain safeguarding activities such as insuring and hedging. Long range investing under rapidly changing conditions … is like shooting at a target that is not only indistinct but moving – and moving jerkily at that. Hence it becomes necessary to resort to such protecting devices as patents or temporary secrecy of processes or, in some cases, long-period contracts secured in advance.

In Alchian's (1951) evolutionary view, innovations may result from bungled imitation as well as from conscious efforts to improve. He considers innovation, like prospecting for natural resources, as a form of search.

It should also be noted that Simon (1951) suggested a stochastic theory of the employment relation resembling Wald's sequential analysis rule. In this remarkable paper, Simon also studied credible threats and promises, reputation and cooperation in a pregame theory environment. He thereby suggested a connection between the two meanings of the 'economics of information.'

No one contributed more to the informal literature on the importance of information to economic decisions than Hayek. While not specifying an explicit search rule, Hayek (1978) clearly saw the importance of the concrete knowledge and special decisions made by millions of dispersed individuals. The key which facilitated the transition from *particular* knowledge to a *specific* decision was the price system:

> The recognition that a man's efforts will benefit more people and on the whole satisfy greater needs, when he lets himself be guided by the abstract signals of prices rather than by perceived needs, and that by this method we can best overcome our constitutional ignorance of most of the particular facts, and can make the fullest use of the knowledge of concrete circumstances widely dispersed among millions of individuals, is the great achievement of Adam Smith.

Thus for Hayek the crucial economic problem is the search for and use of dispersed knowledge whose common source is the price system.

The evolution of job search reveals how useful economic models are generated by *both* formal mathematics and common sense. The origin of the mathematical strand may be quite remote from practical applications, while the original intuitive insight may have little if any formal content. Nevertheless, as both strands evolve a threshold emerges. When this threshold is hit, a moment of insight occurs which unifies the two strands into a new economic model, illuminating a whole set of previously invisible phenomena. The success of the new approach is gauged by empirical data analyzed by novel econometric procedures that are frequently novel.

The Formal Development of Search Theory

See Lippman and McCall (1993) for further detail.

Stopping rules emerged from a very practical problem: Johannes Kepler's search for a wife in 1613. His procedure was

a version of the secretary problem, which was formally designed by Arthur Cayley in 1875 and rejuvenated more precisely by Leo Moser in 1956. (See Ferguson (1989) for a scholarly treatment of the secretary problem's evolution.)

In 1961, D.V. Lindley solved the following version of the secretary problem. The decision maker selects from n candidates who are presented in random order, with no recall of rejected candidates. The ability of the candidate is revealed at the presentation. This information tells the decision maker nothing about the abilities of the remaining candidates. The payoff function is 1, if the best secretary is chosen, and 0, otherwise. The optimal policy for large n is to interview and reject n/e of the candidates, and then choose the next candidate with the highest rank observed. The probability of choosing the best candidate is $1/e$, where e equals 2.718.

In 1960, MacQueen and Miller posed and solved the house-hunting problem. Independent, identically distributed offers $X_1, X_2, \ldots$ arrive one at a time. The return from stopping after n observations is $R_n = \max(X_1, \ldots, X_n) - nc$. MacQueen and Miller found the stopping rule N which maximized ER_N, where E is the expectation operator.

In 1961, Stigler formulated his fixed sample size model. The buyer obtains n price quotations for the item he wishes to purchase. A cost c is incurred each time a quote is made. The mathematical formulation of Stigler search is: choose the sample size n to minimize $E\min\{X_1, \ldots, X_n\} - nc$.

In 1970, the house-hunting problem was applied to job search in a simple model by McCall. The fixed sample size of Stigler's model is replaced by a stopping time N and the sequential decision model of search is given by: select a stopping time N to maximize $E\max\{X_1, \ldots, X_n\} - Nc$.

The optimal stopping time is: accept the first offer which exceeds the reservation wage ξ. The reservation wage ξ is the solution to the first-order condition

$$c = \int_x^\infty (y - x)\mathrm{d}F(x) \equiv H(x) \qquad [1]$$

where $H(x)$, the marginal gain from one more offer, is strictly decreasing and convex. The first-order condition has ξ as its unique solution since $H' < 0$. The economic interpretation of the first-order condition is: equate the marginal cost c of taking an additional offer with the expected increase in the return from taking one more search. It has been shown that ξ is the expected return from search (see Lippman and McCall, 1976). The time until an acceptable offer is obtained, a period of frictional unemployment, is a geometric random variable with mean $[1 - F(\xi)]^{-1}$.

Equilibrium Price (Wage) Dispersion

Rothschild (1973) raised the important question of the existence of an equilibrium price dispersion, namely, what gives rise to the nondegenerate price distribution assumed in simple search models. This question provoked an enormous literature on equilibrium search models which sought a positive answer to Rothschild, thereby negating Diamond's (1971) finding that all sellers charge the monopoly price. In Diamond's model, buyers are identical, sellers are identical, and buyers have the same search cost. If the rules are reversed – buyers instead of sellers make take-it-or-leave-it offers and sellers incur search costs – then markets clear at the competitive price. The preferred way out of this dilemma is to introduce heterogeneity into the model. In McMillan and Rothschild (1993), there are several sources of heterogeneity among the 31 papers surveyed. They include differences in sellers' production costs, buyers' search costs, buyers' beliefs about the offer distribution, sellers' time varying prices, buyers' inventory holdings, and advertising which yields differential buyer information. Burdett and Mortensen (1998) obtain a unique equilibrium solution to a game where a continuum of employers establish wage offers and a continuum of workers search sequentially. If workers search when unemployed *and* employed, wage dispersion is achieved.

Two-Sided Search and Bargaining

Since the early 1980s, the early one-sided optimization search models have been generalized to two-sided equilibrium search models. This research combines game theory with search theory by introducing bargaining into the formation of matches. The steady-state equilibrium is the intersection of best reply functions for workers and employers, i.e., a Nash equilibrium, *when utility is nontransferable*. If utility is perfectly transferable, the matched pair bargains until either an agreement or an impasse is reached. The Nash solution is the equilibrium of this cooperative game. See Burdett and Wright (1998).

McMillan and Rothschild (1993) note that the joint study of bargaining and search fortifies each. In the search theory used by Diamond (1971) and in the price dispersion models described above, after a seller is located by the searching buyer, the seller presents a take-it-or-leave-it price offer. But in many circumstances these offers lack credibility, i.e., the seller has an incentive to bargain if his offer is rejected by the buyer. In bargaining theory, it is usually assumed that a single buyer and a single seller are locked in their negotiations. In fact, each often has the option of searching for another trading partner.

Econometric Methods

The sequential search model gave rise to a sequence of novel econometric methods beginning with the work of Heckman and Singer; and Kiefer and Neumann. Structural estimation has been developed to estimate sophisticated models that have grown from the simple sequential model.

The impetus for structural estimation was Lucas' insight that reliance on reduced-form estimation in policy analysis gives rise to systematic forecasting errors. This insight is a consequence of the rational expectations hypothesis, which is a version of the Nash equilibrium. Thus, the estimation of search models relies on the pillar of contract and incentive models. Indeed, most structural estimation has been conducted within Markov decision processes. These processes are natural for modeling stochastic sequential decision making. Control variables d_t and state variables s_t, $t = 1, \ldots, T$ characterize the decision process. The individual is represented by three primitives: a utility function $u(s_t, d_t)$ denoting preferences at time t, a Markov transition probability $p(s_{t+1}|s_t, d_t)$ denoting the agent's beliefs about future states given current states and

decisions, and the discount factor β. The optimal decision rule δ is obtained via dynamic programming. See Gotz and McCall (1980) for an early application.

An error term ε_t is usually imbedded in the discrete decision process. This insures that the econometric model is nondegenerate. The structure of the error term is determined by the specifics of the problem. The error term is a fundamental element of the overall optimization, a remarkable rise in its stature compared to earlier econometric models. It is now considered an unobserved state variable, the usual state variable s_t being decomposed into (x_t, ε_t), where x_t is a subvector observed by the econometrician and ε is observed only by the agent.

Rust (1994) identifies practical and theoretical reasons for the recent interest in structural estimation. Theoretically, "structural estimation is the most direct way to assess the empirical validity of a specific Markov decision process model." On a practical plane, "structural models can generate more accurate predictions of the impact of policy changes than reduced-form models." This practical reason lies at the heart of the Lucas critique: reduced-form estimates are unreliable forecasts of policy changes because they ignore the impact of policy on the 'deep parameters' (u, p, β). Wolpin (1995) is an excellent survey of this literature by one of its founders.

The Effects of Labor Market Policies in Equilibrium Search Models

Over the past decade there has been an increasing interest in economic models that study the flow of jobs and workers among diverse states. Most of this research relies on equilibrium models and emphasizes the frictions in both search and recruiting. Using a rich set of data on flows in labor markets, this research studies job creation, job closure, unemployment, and labor mobility. Matching and equilibrium are crucial to the theoretical approach. Decisions made by employers on the demand side of the market are highlighted. A comprehensive review of this prodigious literature is Mortensen and Pissarides (1999).

Ljungqvist and Sargent (1995a,b) have devised sophisticated extensions of the simple sequential search model to study equilibrium unemployment behavior in European countries. In Sweden, they recommend a smoothing of the distorted incentives in the labor market by adopting less generous unemployment benefits. In European welfare states, their equilibrium search model finds that:

> when the generosity of unemployment insurance increases, the upward pressure on the unemployment rate eventually dominates the reduction in labor mobility due to high marginal income taxes. The higher unemployment rate is caused by unemployed workers reducing their search intensity and increasing their reservation rates. Higher unemployment pushes taxes upward which in turn increases the unemployment rate further, and so on.

Contracts, Incentives, and Asymmetric Information

Introduction

The past two decades of the twentieth century have witnessed dramatic changes in economic theory. Several years ago most graduate texts in economic theory were founded on price theory. Today, in the major economic departments, economic theory revolves around noncooperative game theory. Price theory has been relegated to the back seat. Before the ascendance of game theory, the emphasis in economics was on the usefulness of economic models in explaining empirical phenomena. While this emphasis persists, it has been overshadowed by the quest to apply strategic thinking to resolve economic problems.

The key ingredients of this remarkable transformation are: the Nash equilibrium (NE) concept, Harsanyi's characterization of contracts with asymmetric information as noncooperative games, and Selten's explicit consideration of time and the elimination of equilibria associated with noncredible threats and promises.

Nash's equilibrium is a strategy for each player where each strategy is a best response to the strategies of the other players in the *n*-person noncooperative game. This concept pervades economics. As a simple example, consider the traveler who drives a car first in the US and then in the UK. He drives on the right-hand side of the road in the US as does everyone else. When he visits the UK, his best response to British drivers is to drive on the left side. These Nash equilibria are akin to rational expectation's equilibria.

The NE is not immaculate. Jack Hirshleifer (private communication), sees

> two major problems with NE: (1) Each player's decision is supposed to be a 'best reply' to the opponent's corresponding choice. But the Nash protocol requires simultaneity. Thus, neither side knows the opponents' strategy to which it is supposed to be replying optimally. Without that knowledge, how can someone make a 'best reply'? … (2) … the 'best reply' has to be to the opponent's strategy, and not just to his observed actions or moves. In all but the very simplest cases, only a tiny fraction of a player's full strategy will ever be visible …. So in general the player can never know whether his current strategy is or is not a 'best reply' to what the opponent has in mind. … NE is fine for 'toy worlds' of our textbooks, but I remain skeptical of its general predictive validity.

van Damme and Weibull (1995) observe that "John Harsanyi showed that games with incomplete information could be remodeled as games with complete but imperfect information, thereby enabling analysis of this important class of games and providing a theoretical foundation for 'the economics of information'." Signaling, moral hazard, and adverse selection are prominent members of this class. A game is said to be one of *complete information* if Nature makes the first move and this move is observed by all players. A game has *perfect information* if each *information set* – the set of nodes in the tree such that one is known to be the actual node – is a singleton. (See Rasmusen (1989).) Harsanyi adopts a Bayesian approach assuming that each player may be of several types – a type specifies the information a player possesses regarding the game. The resulting refinement of Nash's equilibrium is called a Bayes–Nash equilibrium.

Reinhard Selten was the first to refine the Nash equilibrium for analysis of dynamic strategic interactions. Such refinement is necessary since many equilibria entail noncredible threats and do not make economic sense. Selten's formalization of the requirement that only credible threats should be considered, the concept of *subgame perfect equilibrium*, is used widely in the

industrial organization literature. It has generated significant insights there and in other fields of economics.

At first it was not clear how the problems of asymmetric information could be formulated as noncooperative games. Indeed, much significant research in signaling and insurance was performed in the 1970s with little reference to game theory. These models generated important economic implications, but were stymied by problems of equilibrium and credibility. This was changed suddenly when fundamental papers by Kreps and Wilson (1982) and others showed that this research could use the deep insights of Harsanyi and Selten to illuminate credibility and equilibrium. The ensuing unification of industrial organization was analogous to the epiphany that occurred in search theory when optimal stopping, dynamic programming, and matching were applied to search problems.

Principal-Agent Models

This section is a brief discussion of three of the most important asymmetric information models: moral hazard, adverse selection, and signaling. All three belong to the class of principal-agent models. In these models, the principal P designs the contract. The agent A either accepts or rejects the contract depending on the expected utility of the contract vis-à-vis the utility from other alternatives. Finally, the agent performs the task specified by the principal. The two parties are opposed in that the revenue for the agent is a cost for the principal and the effort of the agent is costly to him and beneficial to the agent. In determining the optimal contract between principal and agent, this opposition must be resolved. Macho-Stadler and Perez-Castrillo (1997) see this as "one of the most important objectives of the economics of information."

There are two parties to a P–A model. One is informed while the other does not know a crucial piece of information. For example, in the insurance P–A model, the insurance company is the principal and the insuree is the agent. It is usually assumed that the agent knows his health status, whereas the principal is uncertain. The P–A model is a bilateral monopoly. Hence, the nature of the bargaining process must be specified. For simplicity, it is assumed that either P or A receives all of the surplus. For example, P does this by stipulating a 'take-it-or-leave-it' contract, which the agent either accepts or rejects. Salanie (1997) notes that bargaining under asymmetric information is very complicated: "There is presently no consensus among theorists on what equilibrium concept should be used." Salanie observes that: "the P–A game is a Stackelberg game in which the leader (who proposes the contract) is called the principal and the follower (the party who just has to accept or reject the contract) is called the agent."

The actual bargaining in a concrete setting is unlikely to have this 0–1 structure, where the game terminates if either an agreement or disagreement happens. Instead, the bargaining may continue or, more likely, the disgruntled agent will search until he finds an acceptable contract. Such a model would combine the P–A analysis with search theory.

Three Principal-Agent Models with Asymmetric Information

Moral hazard occurs when the agent's actions are not observed by the principal. More specifically, moral hazard is present when the subject's actions are: (1) influenced by the terms of the contract, and (2) in a way that is not fully specified in the contract. These hidden actions are evident in automobile insurance contracts, where the driving behavior of the insuree is not known by the insurance company. The contract usually has a deductible to mitigate the risk to the insurance company.

Adverse selection occurs when the agent is privy to pertinent information before the contract is finalized. This information is hidden from the principal. Adverse selection is evident in health insurance contracts where certain characteristics (health status) of the agent are imperfectly known by the insurance company. An insurance contract is designed for each group with a particular health characteristic (sickly or healthy) so that each member of the group has an incentive to buy it.

Signaling occurs when one of the parties (the agent) to the contract has pertinent information regarding his type. Before entering the contract, the agent can signal the principal that he has this type, i.e., the behavior of the informed party conveys (signals) the type information to the uninformed party.

A key observation is that each of these asymmetric information models can be represented as a noncooperative game. The crucial equilibrium concept is a refinement of the Nash equilibrium. For example, the signaling game has a perfect Bayesian equilibrium. Excellent discussions are given in Gibbons (1992) and Macho-Stadler and Perez-Castrillo (1997).

One of the most important topics in the economics of information is the optimal design of contracts under symmetric and asymmetric information. In the symmetric case, the principal designs the contract so that the expected marginal payoff equals the marginal cost of effort. If the principal is risk neutral, then the optimal contract is one in which the principal accepts all the risk and the agent is, therefore, fully insured, receiving a payoff that is independent of the outcome. In the asymmetric case, the situation is much more complicated. The optimal contract balances the conflict between two opposing goals: efficiency in the allocation of risk between principal and agent and maintaining the incentives of the agent. For lucid presentations of the analysis, see Macho-Stadler and Perez-Castrillo (1997) and Salanie (1997).

Future Developments

It seems clear that the merger between search and game theory will continue. The benefits from this include: strategic thinking will become even more apparent in search models and the econometric testing of game theory models should develop into a cottage industry alongside experimental testing. Search models will continue to be used to evaluate labor policies like cross-country unemployment and other macro issues. Their use in other economic areas should also flourish.

In his evaluation of the applications of Nash equilibrium, Selten claims that we still know little about actual behavior and that empirical research and theories of bounded rationality are needed. Rubinstein (1995) is more emphatic. "Economic theory should deal with the real world. It is not a branch of abstract mathematics even though it utilizes mathematical tools. Since it is about the real world, people expect the theory to prove useful in achieving practical goals. But economic theory has not delivered the goods." Many would dispute the final sentence, but

most would agree that game-theoretic models require extensive econometric testing. This has already begun, with structural estimation being the favored method, but much remains. This is an exciting time for the economics of information.

Information Theory

Laura Martignon, Ludwigsburg University of Education, Ludwigsburg, Germany

Abstract

Information theory is the mathematical treatment of the concepts, parameters, and rules governing the transmission of messages through communication systems. It was founded by Claude Shannon toward the middle of the twentieth century and has evolved into a vigorous branch at the interface between mathematics and communication theory, fostering the enrichment of other scientific fields, such as biology, behavioral science, neuroscience, and statistical mechanics. The techniques used in information theory are probabilistic in nature, and some view information theory as a branch of probability theory. In a given set of possible events, the information of a message describing one of these events quantifies the symbols needed to encode the event in an optimal way. 'Optimal' means that the obtained code word will determine the event unambiguously, isolating it from all others in the set, and will have minimal length, that is, it will consist of a minimal number of symbols. Information theory also provides methodologies to separate real information from noise and to determine the channel capacity required for optimal transmission conditioned on the transmission rate.

Introduction

Radios, telephones, televisions, and, last but not least, computers are devices that store, process, and communicate information; today they belong to the basic equipment of the average citizen in the industrialized world. It is no exaggeration to claim that the twentieth century witnessed the greatest revolution of communication and information technology since the invention of the printed book. This vigorous development created the need for a well-founded theory and a rigorous terminology that would allow discussion about information with scientific precision. In 1948, the American electrical engineer Claude Shannon provided a synthesis of the fundamental ideas of what is now considered the classical theory of communication (1948). In his seminal paper he wrote that the fundamental problem of communication is that of reproducing at one point, either exactly or approximately, a message selected at another point (Shannon, 1948). Information theory is the conceptual framework in which Claude Shannon solved main aspects of this problem.

For the sake of historical precision it should be noted that some of Shannon's ideas had already been put forward, although in less rigorous terms, by Hartley (1928). Yet it was Shannon's achievement to set information theory on firm theoretical grounds. He also discovered the basic mathematical laws of systems that communicate information. Separating relevant information (signal) from irrelevant information (noise) was one of the problems Shannon tackled and solved. Another problem that Shannon essentially solved was the setting of upper bounds on what can be achieved with a given information-carrying medium or channel. For these seminal contributions to information theory, Shannon is considered its founder.

In telephony for instance, there is a source of information, namely a person speaking into a telephone. The message is the sound that is produced, while the transmitter is composed by the microphone and the equipment that changes this sound into an electromagnetic wave, which becomes the signal. The channel is the space between the transmitting and the receiving telephone, that is, the receiver. Any static or other phenomenon distorting the signal is called noise. An unambiguous specification of the particular message chosen by the information source has to be transmitted so the original message can be reconstructed at the receiving point. The receiver reconverts the received signal into an audible sound. Information theory deals with the problem of specifying a quantitative relation between a given message and the set of all possible messages from which it is chosen (see **Figure 1**).

Quantifying Information

Imagine a simple game for two players: one player thinks of a number between 1 and 64 and the other has to guess what the number is by asking only questions that can be answered by 'yes' or 'no.' The strategy followed by a player could be, for instance, to begin by asking the question: Is the number less than or equal to 32? If the answer is, say, yes, then the player

Figure 1 A typical channel for information transmission.

could ask whether it is less than or equal to 16. If the answer is, say, no, then the remaining set of candidate numbers is 17, 18, 19, …, 32. One possible optimal question at this moment – clearly not the only optimal question – would be: Is the number less than or equal to 24? Clearly, the minimum number of yes–no questions required to determine the number for certain is 6. Roughly speaking, the amount of information contained in the message describing an event out of a set of possible events corresponds to the number of yes–no questions needed to isolate that event from all others in the set, following an optimal strategy. If, in the previous game the number to be guessed were, for instance, 23, then the sequence yes-no-no–yes-no-yes, beginning from right to left, is a code for the number 23 that corresponds to the strategy described herein and the specification of the message would then be this ordered sequence of yes and no obtained as answers. The unit for measuring information is the bit. One bit of information corresponds to a message describing one event out of two equally likely events. Two bits correspond to a message describing an event out of four equally likely events. One event out of $N = 2^d$ likely events has d bits of information, or, in a somewhat more suggestive form, it has $-\log_2 1\ N^{-1}$ bits of information (see Figure 2).

If an event with probability N^{-1} has $-\log_2 N^{-1}$ bits of information, it appeared natural to Shannon to extend this measure to an event with probability p by establishing that it must have $-\log_2 p$ bits of information. It was shown by Shannon that the negative logarithm of the probability is the only function satisfying all the properties one expects from information (see also Luce, 1960). Characterizing the properties of this measure for information and the concepts related with it was one of Shannon's breakthroughs. Given a set of N events with probabilities $p_1, p_2, \ldots, p_N$, the amount of information associated with the i-th message is $-\log_2 p_i$ so that the expected value of information per message is given by

$$H = -\{p_1 \log p_1 + p_2 \log p_2 + \cdots + p_N \log p_N\}.$$

This quantity represents the uncertainty contained in the source. Shannon had originally called this expression the average information of the message set. It was John von Neumann who convinced Shannon to introduce the term 'entropy' for average information, seeing the natural connection between average information and entropy in thermodynamics. The term stems from thermodynamics and was introduced by Rudolf Clausius, who formulated the second law of thermodynamics in 1850 (the entropy of an isolated system is always increasing until it reaches its maximum). He composed the term 'entropy' with the Greek roots tropein (turn) and *en* (into) in analogy with the term 'energy.' Entropy takes on its smallest value, zero, when there is one message that is certain to occur (i.e., the described event has a probability 1) and all other messages never occur. Intuitively, there is no information in a message that was a priori certain. Maximal entropy occurs when all messages are equally likely, which corresponds to the situation of greatest uncertainty about outcomes. The ratio of the uncertainty of a source to the maximal entropy possible on the same set of symbols is the relative entropy of the source and

$$\text{“}1 - \text{relative entropy”}$$

is the redundancy of the source. The specification of a message as a (finite) sequence of binary symbols (say, for instance, 0 for no and 1 for yes) is called a 'code word' for the message. An important feature of the average information, H, is that it determines the saving in transmission time that is possible, by proper encoding, because of the statistics of the message source.

Based on the concept of information, Shannon introduced measures for information rate as well as for channel capacity. He stressed the fact that information has all the properties of matter: it can be transported, compressed, and segmented into small pieces. The diagram in Figure 1 can be viewed as a transportation system. The channel can be seen as transporting matter from a source to a receiving site. In this situation, there are two important quantities: the rate at which information is produced at the source and the capacity of the channel. Obviously if the rate of production is greater than the capacity of the channel, it will be impossible to transport the full output of the source. Suppose, however, that there is a device – the encoder – at the source that, just like a mill, cuts

Figure 2 Quantifying information.

information into smaller pieces, then 100% efficiency can be achieved. Shannon proved that if the information rate at the source is less than the channel capacity, then encoders and decoders can be constructed such that the source output is recreated at the destination with as small an error probability as desired. Conversely, if the information rate at the source is greater than the capacity, then the error probability cannot be made arbitrarily small.

Information and related concepts have led to a unified and theoretically sound treatment of uncertainty and reduction of uncertainty in statistics and decision theory. In the set of all distributions on a finite sample space, the distribution that maximizes entropy is the uniform distribution, for which all single elements are equally probable. Laplace's 'uncertainty principle' (1812) advised to assume that a distribution is uniform, whenever no further knowledge is at hand. For far more than one century probabilists and statisticians searched for an adequate extension of the uncertainty principle to the case when partial information on a distribution is available. Information theory provided the ideal extension via the concept of entropy: it was called the 'maximum entropy principle,' or 'MaxEnt.' It states that whenever some of the marginals of the distribution are known, one should assume that the distribution is the one – and only one – that maximizes entropy in the set of all distributions with those marginals. By doing this one guarantees that no additional information is added to the distribution. A family of important algorithms has been developed for the construction of the MaxEnt distribution (Bishop et al., 1975). The MaxEnt principle and algorithms for constructing the MaxEnt distributions form the fundamental ingredients for the designation of a priori distributions when events are not equiprobable.

An excellent, modern survey of information theory and its applications was provided by Cover and Thomas (1991).

Information Theory Applied in Psychology

Information theory has had a major impact on behavioral science and on cognitive neuroscience. Psychologists have discovered important relationships between the amount of information in a stimulus and reaction time to the stimulus. An important finding concerns the adaptation of participants to the statistics of information conveyed by presented stimuli and their ability to recognize redundancy of information in stimuli. This leads to shorter reaction times. Another important finding concerns human short-term memory: Pollack (1953) and Miller (1956) noted that basic information is coded in 'chunks.' The ability to form chunks enables organisms to make better use of their limited capacity short-term memory. Because short-term memory appears to be capable of holding only five to seven chunks, efficient information processing depends on the ability to pack more information into a single chunk. Grouping into doublets (two-bit-chunks) and recoding (e.g., 00 = A, 01 = B, 10 = C, 11 = D) can double the number of bits that can be held in short-term memory at a given time.

Forming triplets or larger groupings further increases the number of memorized bits in a nonlinear way. But, there are constraints to this procedure. Chunking is only effective with sufficiently long presentation times. With presentation times under 0.5 s, no successful grouping takes place (Kleinberg and Kaufmann, 1971). Yet with presentation times of 1 s and longer there is a clear advantage in using chunks. An excellent, by now classical, survey of applications of information theory in psychology was provided by Attneave (1959).

Information theory has allowed a treatment of redundancy in language. For example, the sentence 'Sm mn in ths rm us glsss' can be understood as 'Some men in this room use glasses,' although several vowels have been deleted. Shannon studied the redundancy of English language and discovered that English texts can be reconstructed when 50% of the letters, chosen at random, are deleted. Other important applications of information theory deal with word perception. If the source vocabulary is small, humans are able to perceive words nearly perfectly, whereas perception becomes increasingly difficult as the source vocabulary becomes larger (Miller and Selfridge, 1950).

Information Theory Applied in Neuroscience

In cognitive neuroscience, information theory has become an essential tool for understanding brain function. Modeling the brain as an information processing machine has led to important advances in both theory and practice. The production of action potentials (spiking) of neurons can be discretized and interpreted as a binary process. In this way, a temporal sequence of spikes can be represented as a binary vector of 0 and 1. All information coming from sensory inputs is processed by neurons using this simple binary language. Hebb (1949) conjectured that neural information processing cannot be understood just in terms of the behavior of individual neurons. Rather, the brain must be viewed as a system of so-called cell assemblies, wherein information processing occurs as an emergent property resulting from the interaction of these cell assemblies. Hebb's conjecture received a great deal of experimental confirmation in the last decades of the twentieth century (Gray et al., 1989). The famous binding problem, or problem of identifying an object by recognizing individually and 'binding together' features that characterize the object, appears to be solved by means of synchronization of spiking activity (Singer et al., 1994). Theoretical neuroscientists have developed many different approaches to modeling how information is stored in the brain. The most convincing and persistent model has been the associative memory (e.g., Palm, 1980) that stores similar patterns close to each other, where the closeness between patterns is measured in terms of information overlap.

Informed Consent of Research Subjects

Paul S Appelbaum, Columbia University, New York, NY, USA; and New York State Psychiatric Institute, New York, NY, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

'Informed consent' denotes a person's autonomous agreement to a proposed course of action, usually in a treatment or research context. The principle that research requires the informed consent of participants is accepted around the world. Elements necessary for consent to be informed include disclosure of relevant information, adequate decision-making capacity, and absence of coercion or undue influence. Challenging issues characteristic of social and behavioral research include use of deception; necessity of consent for record-based research; informed consent in observational research and fieldwork, and for Internet-based research; and role of community consent.

'Informed consent' denotes a person's autonomous agreement to a proposed course of action, usually in a treatment or research context. Consent is not considered to be informed unless the person has received disclosure of the information that a reasonable person would consider material to the decision at hand; has the capacity to use that information in a rational process of decision making; and reaches a decision in the absence of coercive offers or threats (Berg et al., 2001). Broad agreement exists that informed consent is an indispensable requirement for the ethical conduct of research with human subjects, at least when the research renders them liable to more than minimal risks of harm. However, considerable controversy remains regarding the precise contours of the doctrine and of the circumstances that might constitute exceptions to the general rule. Since the rules have been devised largely with biomedical research in mind, issues more characteristic of social and behavioral science research have been relatively neglected.

History of Informed Consent to Research

The history of informed consent to research is usually traced back to the decision of the court in the Nazi doctors' trial at Nuremberg after World War II, which declared, 'The voluntary consent of the human subject is absolutely essential.' It is clear, however, that the Nuremberg tribunal neither originated nor established the concept of consent to research. References to requirements for consent from research subjects can be found in the writings of physician experimenters and in governmental pronouncements dating back to the late nineteenth century, when experimental medicine grew out of its infancy (Lederer, 1995). Indeed, George Bernard Shaw's *Pygmalion* contains an explicit statement of the principle. Two of the leading instances, ironically, derive from Germany, where the advanced state of empirical medical science made consent an object of at least periodic concern (Grodin, 1992). Nonetheless, however much the Nuremberg court desired to root the principle in contemporary practice, it appears that researchers in many countries, even after the Nazi atrocities came to light, frequently failed to obtain consent from their subjects.

Nor did the Nuremberg decision immediately change these practices. Investigators using human subjects apparently saw the Nuremberg Code, as the 10 principles embodied in the court's decision came to be known, as applying only to the anomalous situation of concentration camp inmates. Thus, the history of the postwar decades is marked by repeated revelations of questionable ethical practices, including studies in which persons were subject to clear harms without their knowledge or consent (for one of the most influential reports of problematic studies, see Beecher, 1966). Pressure built for clearer rules and mechanisms of enforcement.

The World Medical Association responded to these concerns with its *Declaration of Helsinki* in 1964 (World Medical Association, 2008), the first attempt to forge an international professional consensus on the ethics of research. The *Declaration* endorsed a requirement for informed consent, albeit in less sweeping terms than the Nuremberg Code; subsequent iterations of the document have brought increased rigor to the mandate for consent of human subjects. National professional organizations developed similar documents, but their nonbinding character left research subjects with few certain protections.

A move toward legally enforceable rules came in the USA in 1974, in the wake of disclosure of the Tuskegee study, in which African-American men in Alabama, without their knowledge, had been denied treatment for syphilis for more than four decades, ostensibly for the sake of observing the natural course of the disease (Jones, 1981). The federal legislative response to the scandal included the appointment of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, which was charged with generating recommendations for closer oversight of research with human subjects. One of its major products, The Belmont Report (1979), laid out the ethical underpinnings of human subjects research, locating a requirement for informed consent in the principle of 'respect for persons,' which required that "subjects, to the degree that they are capable, be given the opportunity to choose what shall or shall not happen to them." The Commission's reports stimulated the adoption of regulations governing federally funded research. Most of the countries in the world have since followed suit, by way of legislative or regulatory enactments, or binding guidelines (for a summary of the status of research regulation in 103 countries internationally, see Office for Human Research Protections, 2014). The general principle that research should not be conducted

without the informed consent of participants has been accepted around the world.

Current Contours of Informed Consent to Research

The requirements for informed consent to research are rooted in the ethical principle of autonomy, which demands respect for the free, informed choice of a competent person (Faden and Beauchamp, 1986). Valid informed consent requires three elements to be present: disclosure, decision-making capacity, and voluntariness.

Disclosure

The Nuremberg Code (1948) declared that the research subject "should have sufficient knowledge and comprehension of the elements of the subject matter involved as to enable him to make an understanding and enlightened decision." Brody (1998) summarized the international consensus regarding those items that need to be disclosed to achieve this end as follows:

1. "The purpose and the research nature of the project;
2. The duration of the subject's participation, the treatment and procedures that the subject will undergo (with a clear specification of which are experimental), and the subject's responsibilities;
3. The risks of harms and discomforts that might result from participating in the research;
4. The possible benefits to the subject or to society from the research;
5. The alternatives to participating in the research;
6. The right not to participate and to stop participating at any time without penalty or loss of benefits to which the subject is otherwise entitled;
7. The measures to protect confidentiality;
8. The anticipated payments, if any, to the subjects and the anticipated expenses, if any, that will be borne by the subject;
9. The compensation and treatment available for injuries sustained in the research;
10. The identity of a contact person to discuss questions about the research;
11. The circumstances under which the subject's participation will be terminated;
12. The assurance that new information relevant to participation that becomes available during the research will be provided to the subject;
13. The names of the sponsors of the research and the ownership of any commercial results."

This information is generally provided in written form, though often supplemented by verbal disclosures. Frequently, the result is a lengthy form (20–30 page, single-spaced forms are not uncommon in clinical research), filled with a combination of medical/scientific and legal jargon, that is difficult for potential subjects to read and assimilate. Provision of a mass of detailed information means, moreover, that important data, such as those dealing with significant risks, are frequently neglected by subjects. A common resulting problem is the so-called 'therapeutic misconception' – a belief on the part of subjects that procedures are being undertaken for their benefit (including randomization and use of placebos), when they are actually designed solely to advance the research effort (Appelbaum and Lidz, 2008).

A substantial empirical literature documents the failure of this process to result in well-informed research subjects. Consent forms are routinely written at a reading level well beyond the comprehension of the average subject and considerably exceed the amount of information to which most people will attend (Albala et al., 2010). Though investigators are often urged to provide additional disclosures in more understandable formats (e.g., illustrated brochures that subjects can read at their leisure), this still represents the exception rather than the rule. However, there has been a good deal of experimentation with the use of augmented means of disclosure, including iterative educational interactions, hyperlinked computer-based methods, and interactive video disclosures. The data on the efficacy of these approaches are variable, but in at least some studies encouraging results have been achieved (Ryan et al., 2008; Schenker et al., 2011).

Decision-Making Capacity

The subject's capacity (often interchangeably referred to as competence) to give a meaningful consent was considered a *sine qua non* in the Nuremberg Code. Although formulations of the requirements differ somewhat across jurisdictions, decision-making capacity generally involves the abilities to understand the information relevant to a decision, to appreciate its implications for one's own situation, to reason in a rational fashion, and to evidence a choice (Appelbaum and Grisso, 2001).

Capacity is generally presumed to be present, unless there is reason to believe otherwise. Indeed, studies of general medical patients show extremely high rates of capacity and indicate that, as a group, they tend not to differ from the general population in their decision-making abilities. Although studies of populations at elevated risk of incapacity, including persons with severe mental disorders, mild dementia, head injury, and the like, show higher rates of decisional impairment, many of these patients remain capable of making their own decisions about participation in research (Appelbaum, 2006). Particularly when the research may present significant risks to these groups of participants, investigators are increasingly assessing capacity prospectively. This can be done by clinical evaluation or formal screening instruments, with the latter offering a means of structured assessment, standardized scores, and the ability to compare performance across individuals and groups (Dunn et al., 2006). Identification of a potential subject as having impaired capacities does not necessarily mean that the person must be excluded from research participation. Many such persons can be brought to acceptable levels of functioning with additional educational efforts or interventions that address the underlying cause of their impairment, and ultimately allowed to make their own choices about participation.

Were capacity to be an absolute requirement, as the Nuremberg Code suggested, no research could be conducted with children – who lack capacity as a matter of law – or with

many patient groups, including potential subjects who are comatose, suffering from moderate to severe dementia or intellectual disability, or severely psychotic and disorganized. The desirability of allowing research with these groups, so that progress might be made on the disorders from which they suffer, led the drafters of the Declaration of Helsinki, and most subsequent compilers of codes, regulations, and statutes, to make some provision for the entry of incapable subjects into research projects. Typically, a surrogate decision maker appointed by the potential research subject prior to incapacity or otherwise designated to make medical treatment decisions is permitted to provide informed consent on behalf of an incapable subject. Rules governing the inclusion of incapable persons in research differ, but common limits include that the research be directly applicable to their conditions, not able to be performed with capable subjects, hold out the prospect of some therapeutic gain, or present no more than minimal risks of harm. Mechanisms that would allow persons to make advance decisions while competent about whether to enter research projects should they later become incompetent are beginning to be introduced (under the generic rubric of 'research advance directives'), paralleling similar mechanisms that have been developed for treatment settings.

Voluntariness

Overt coercion – the application of threats or unfair offers to a prospective research subject – is universally recognized as vitiating that person's decision and thus rendering consent invalid. The effects of more subtle influences on the legitimacy of subjects' consent to research are a matter of greater controversy. Recent studies suggest that most research participants do not perceive themselves as having been exposed to illegitimate pressure regarding enrollment in a study (Appelbaum et al., 2009). However, some environments may be considered so intrinsically coercive – prisons, for example – that research with the persons detained therein has been severely restricted in many countries. Whether hospitals, institutions for the mentally ill or intellectually disabled, schools and colleges, places of employment, and other entities fall into that category is more difficult to say. Paradoxically, efforts to protect inmates, patients, workers, and others by prohibiting their participation in research deprive them of their residual decision-making power, and may increase their feelings of helplessness and their perceptions of being coerced. Indeed, some recent data suggest that prison inmates do not perceive themselves as vulnerable to coercion with regard to making decisions about research participation (Edens et al., 2011).

Research subjects are often compensated for their participation with money or its equivalent, a practice that has engendered a great deal of confusion among investigators and regulators regarding its appropriate limits. Fair compensation for the time expended in a study is generally considered acceptable. However, to the extent that payment is so substantial as to lead subjects to give insufficient attention to the risks they may run by participating, it may be considered an undue influence on their decisions (a condition different from coercion, with which it is often confused), which renders their choices substantially involuntary. Some commentators have argued that compensation for research participation is similar to payment for any other job, and hence is intrinsically incapable of subverting free choice (Emanuel, 2005). Although this remains a minority view, many research ethicists concur that restrictions on payment of subjects have been unnecessarily rigid, with the unintended result that participants' contributions receive less reward than they deserve.

Special Considerations in Behavioral and Social Science Research

Rules governing informed consent to research, from the Nuremberg Code to most contemporary governmental regulations, typically have been formulated with biomedical research in mind. Issues more characteristic of social and behavioral research have been relatively neglected. Indeed, the federal regulations in the USA categorically exempt many types of behavioral and social research from their purview, including educational research; studies designed to evaluate governmentally provided benefits or services; and testing, surveys, interviews, or observations of public behavior, unless information is recorded in a manner that would render subjects identifiable, and subjects would be likely to suffer harm if the information were released (Code of Federal Regulations, 1991).

Even so, many behavioral and social scientists object to what they perceive as a steady expansion of the scope of regulatory attention – sometimes pejoratively characterized as 'mission creep' – embodied in the USA in requirements for prospective review of their studies by institutional review boards (often referred to as 'research ethics committees' in other countries). Controversies have erupted over the application of regulatory requirements for research, including requirements for informed consent, to oral history, journalism, ethnographic research, and other approaches that seem very different from the biomedical studies that initially motivated development of the regulations (Schrag, 2010). It is sometimes argued that research oversight restricts behavioral and social science investigators' freedom of inquiry and freedom of speech in ways that are both unfair and detrimental to the research enterprise.

Yet, many behavioral and social science studies involving human subjects raise important issues related to informed consent. One of the major questions is when, if ever, it is appropriate to deceive subjects about the purpose of a research study, a frequent technique in psychological research. Other issues concern consent for access to records, consent in observational and field work studies, and the appropriateness of seeking consent – or some equivalent – from entire communities that may be affected by an intervention that is part of a research project.

Consent in Studies Based on Review of Records

Analysis of existing records, often aggregated into large databases, is a frequent technique used by behavioral and social scientists. These records may have been collected originally with subjects' consent but for nonresearch purposes (e.g., medical records) or without subjects' consent and sometimes without their knowledge (e.g., national birth registries,

educational testing results, census information, or tracking data on Internet utilization). When individual subjects are not reasonably identifiable in the database, it is generally agreed that consent need not be obtained prior to granting researchers access. Even with identifiable data, researchers have often been allowed to utilize such records as long as they agree to protect the confidentiality of those persons whose information they are reviewing (e.g., by publishing data only in aggregate form).

This practice has been criticized as insufficiently protective of subjects' interests in both autonomy and privacy. The autonomy argument is predicated on the belief that persons should have the right to control access to information about them, preventing its use, for example, for research purposes of which they may disapprove. Privacy concerns have been given greater weight of late with the growing ability of researchers to integrate information obtained from different databases about the same individuals, thus accumulating large amounts of information that, were it to be used or accessed for unauthorized purposes, could prove embarrassing or harmful to the people involved. These concerns have grown as new types of information, often collected without people's conscious awareness, have come into being, e.g., cellphone tracking data that permit continuous monitoring of persons' locations and movements. Strong arguments have been made for obtaining consent from the subjects of these records prior to their release for research purposes.

Researchers often object to these proposals on the grounds that they would materially increase the costs of research and, insofar as subjects' refusal of consent would bias the resulting data, decrease the validity of their findings (Institute of Medicine, 2009). In many cases, it will simply be infeasible to track down and obtain consents from the persons whose data are in question. No reasonable argument can be made for precluding researchers' access in these circumstances, so long as the study is of some significant value and appropriate safeguards are in place. When smaller and more recent repositories of data are involved, and obtaining consent would not involve unreasonable expenditures of resources, it is clearly more respectful of subjects' interests to seek their agreement. When records are being compiled prospectively with the intent of using them in the future for research purposes, there is no ethical justification for failing to obtain subjects' consent at the time.

Consent in Observational Studies and Field Work

Many of the behavioral sciences have a long tradition of sending researchers into the field to study the behaviors of persons in their natural environments. This often involves requesting access from those to be observed to otherwise private interactions and territory (e.g., discussions between spouses in the subjects' home, physician–patient interactions in medical clinics). Considerable controversy exists over whether and how truly informed consent should be obtained in such cases. Insofar as researchers may observe and report embarrassing or frankly criminal behavior, subjects may be placed at risk of psychological or tangible harm. Thus, the case for obtaining consent in such studies would seem strong, bolstered by the discomfort some investigators report in withholding this information from their subjects.

On the other hand, researchers have an understandable concern that informing subjects clearly of the goals of their studies may lead subjects to alter their behaviors, thus obscuring the very phenomena that are under study. Though many subjects appear remarkably prone to ignore such information, especially once they become accustomed to the observer's presence, and appear to behave as they would were no observers present, this concern needs to be taken seriously. It should usually be possible to accommodate both parties' interests by disclosing the intent of the study in general terms, along with the likely risks to which subjects may be exposed. If some modification of subjects' behavior occurs, this may be an unavoidable price to pay for acquiring a meaningful consent. In addition, after data collection is completed, the researchers can provide more complete information to the subjects regarding the purpose of the research and the questions it was designed to address. Although such *post facto* debriefing does not vindicate subjects' autonomy and privacy interests as would full prospective consent, it does demonstrate respect for the personhood of research subjects and hence should be encouraged.

Consent in Community Intervention Projects

Social science research increasingly involves large-scale interventions directed at particular communities or segments of a community. These may include interventions designed to avoid undesirable outcomes (e.g., juvenile delinquency, teenage pregnancy, illegal drug use) or to promote what are generally seen as salutary ends (e.g., moving persons off welfare and into paying jobs). When such interventions occur at the level of the community as a whole – such as broad-based educational programs concerning drug abuse – it is impossible to obtain informed consent as it is usually conceptualized. Moreover, when studies are based on changes to entitlement programs that have been enacted through the political process, the consent of individual persons may be seen as irrelevant.

There may, nonetheless, be a role in such instances for a modified form of consent interactions with the relevant community. Although each person's consent cannot be obtained, disclosure of the nature and purpose of the study and its risks and benefits can still take place. Consultation with the community at large and its designated representatives may result in suggestions for modifications in the study culminating in a general consensus concerning its desirability. The growing popularity of the community-based participatory research model (Minkler and Wallerstein, 2008), which represents the next step in the evolution of this approach, is premised on the value of going beyond mere consultation with the community, and involving community representatives in all aspects of research from study design to data analysis as equal participants with the researchers.

Consent in Internet-Based Research

The rapid growth of the Internet since the beginning of the new millennium has made it an attractive venue for research that previously could only have been carried out by face-to-face interaction or observation. Investigators have mined publicly available data to assess, for example, networks of social

relationships and consumer preferences, and have engaged in observation and interaction on social media portals ranging from interactive gaming sites to chat rooms. Although some of the issues related to informed consent that arise in these studies are similar to those in traditional participant-observation research (e.g., will obtaining formal consent so alter subjects' behavior as to vitiate the possibility of obtaining valid data?), the ability of Internet-based researchers to disguise their identity or even presence (i.e., 'lurking' in a chat room) heightens concerns about when consent is required and how it should be obtained. In addition, the possibility of identifying participants and linking their data to other data sets enhances the risks associated with such studies. Moreover, while online postings and interactions often take place in nonprivate domains, studies suggest that participants are frequently unaware of the possibility that their statements and behaviors may be open to public view, and scholars have suggested that consent should be required to mine these data (Zimmer, 2010).

Standards for when informed consent must be obtained online and how that can be accomplished are still in evolution, in part because Internet-based technologies themselves are in flux. The media themselves create technical challenges, for example, when participants in a chat room come and go at will during a period of observation, even if the investigator desires to obtain consent from each participant, how can that be accomplished? Other complexities include the real possibilities that some participants are minors, and hence unable to give valid consent on their own behalf, while others may be located in countries different than the one where the investigator is based, which may have different rules governing research and varying requirements for consent. As this domain of research grows into maturity, it seems likely that a clearer perspective will be obtained on participants' views about the desirability of consent, the probable risks they face from various forms of Internet-based research, the feasibility of obtaining their consent, and regulatory considerations.

The Future of Informed Consent to Research

Imperfect as the process of obtaining consent to research is in practice, it is nonetheless widely considered a bulwark of ethical research with human subjects. However, dissatisfaction with the ways in which consent is obtained has led some scholars to suggest that the goals of the informed consent process should be reconceptualized. Rather than seeing the purpose of consent as vindicating subjects' autonomy, for example, Manson and O'Neil (2007) have suggested that it should be understood as a mechanism for waiving rights to which subjects would otherwise be entitled (e.g., privacy of medical information). A practical consequence of this conceptual difference, they argue, would be a more manageable consent process, one focused on effective communication of a limited range of critical information, as opposed to the current tendency toward massive – and often incomprehensible – disclosure. Similarly disturbed by the failures of many research subjects to absorb consent disclosures, Miller and Wertheimer (2011) argue for a 'fair transaction model' of informed consent, whereby investigators would disclose the information necessary for fair consideration of participation in a study, but without an expectation that subjects would necessary grasp the disclosure in its entirety. They, too, believe that it is unrealistic to expect informed consent to result in fully autonomous decision making, but more explicitly rely on the vetting of research studies by research ethics committees to ensure that potential subjects are not being asked to participate in unreasonably harmful research.

At the same time that these arguments for reconceptualizing consent have been put forward, other scholars have pursued empirical studies that promise to shape for the better a debate that has frequently been waged on theoretical grounds alone. Data on the failings of the current system can point to practical ways of improving the consent process that do not require a reorientation of its goals or changes in regulation. Among the areas of investigation have been participants' views regarding the information material to an informed decision; the adequacy of investigators' disclosures and means by which they can be improved; the prevalence of incapacity among various groups of research subjects; subjects' understanding of the information they have received and their appreciation of its implications for their situation; subjects' retention of information over time; and subjects' perceptions of pressures to consent to participation.

Conducting research on informed consent is often challenging. Naturalistic research on the consent process involves overcoming the reluctance of investigators to grant access to the research setting, and of subjects to consent to participation in yet another research study. Subject recruitment can be both difficult and time consuming. The willingness of funding agencies to sponsor such research is often related to the degree of public scrutiny of and concern about the agencies' research portfolio. But such research is likely to continue to increase over time and to play a greater role in helping to shape investigators' practices, official policies, and theoretical understandings of informed consent to research.

Infrastructure Investment

Abstract

Infrastructure investment is central to urban development, generally conceived of as the physical foundation of the city or, as one historian graphically put it, the 'technological sinews' built to meet the needs of society. More precisely these are the transportation networks, power girds, utility systems, and telecommunicative linkages that deliver the heat, light, water, and power that are central to urban life and without which modern cities would not exist. This foundational primacy affords infrastructure a rather unique status in the literature: namely it is not described simply as an important physical artifact but as an investment in the city-building process. Understanding the political and economic implementation of infrastructure investment is important to understanding the modern city in both the 'developed' and 'developing' urban world. Infrastructure investment links technology to: (1) the organization and constitution of modern governments; (2) public finance and debt policies; (3) the creation and regulation of capital markets; (4) the articulation of public goods; (5) the privatization of governmental services; and (6) the increasing role of nongovernmental intermediaries in markets and states, thereby creating socio-technical networks of service underservice that contribute to the distributions of power and unevenness of development in cities, worldwide.

The city-building process is a product of infrastructure investment. At the most general level, the term infrastructure describes the underlying foundation of the physical and social facilities of the city (Seeley, 1993: p. 20; Konvitz, 1985: p. 130), both the physical systems and technologies, and the health, education, and welfare facilities that knit the city into a collective fabric. From this perspective, Herbert Muschamp (Perry, 1995: p. 1) observes that, "infrastructure is shorthand for the structural underpinnings of the public realm."

While such an encompassing approach to infrastructure has conceptual resonance, most studies carve a more particular focus (OECD, 1991; Neutze, 1997; Graham, 2000), defining infrastructure as the underlying physical foundation of the city: the material systems, networks, and technologies (roads, water and sewer systems, power grids, and telematic networks) that serve key urban relations; the social flows, economic exchanges, and political relations of the city. This foundational primacy of physical infrastructure affords it a rather unique status in the literature: namely, the bridges, roads, and water systems of the city are not described simply as important physical artifacts but as investments in the city-building process. The returns on such investments are measured in terms of a society's economy, health, and social well-being.

Hence infrastructure scholarship and policy often begin with the normative position that the more an urban population is able or willing to invest in physical infrastructure, the more apt the urban settlement is to prosper economically and benefit socially from the resulting conditions of efficiency, health, and human development. This is perceived to be as true in new or emerging urban centers as it is in the established cities of the developed world, thereby making issues of definition, public or private provision of such systems, finance, and technology equally important to every modern city.

Infrastructure: Evolution from Private to Public Function

The term 'infrastructure' as it is employed here is relatively new: a conception of the late twentieth century that is used to describe the systemic applications of technology to the needs of urban society, producing what historian Joel Tarr (1984: p. 4) calls the 'technological sinews' of the city: its transportation networks, power grids, utility systems, and telecommunicative linkages. For much of the nineteenth and twentieth centuries, urban physical facilities were not viewed systemically as 'physical networked services' (OECD, 1991: p. 19), but as either privately produced, geographically individuated 'internal improvements' or equally decentralized, governmentally generated 'public works.'

For example, the seventeenth-century invention of the British toll road, the late eighteenth-century canal systems, and the early railways were initially proprietary responses to the requirements of the Industrial Revolution. Technological advances in water treatment, electricity, gas distribution, and modes of communication were virtually all developed by private inventors and investors. Only later, as the impact of such inventions on the dramatic and uneven shifts in urban populations, levels of disease, congestion, and fire became apparent, did they come to be viewed as a public responsibilities or goods. Even then, cities "different … business leaders, politicians and professionals" (Tarr, 1984: p. 5) would take years to determine which technology or proprietary service was the right one and more years to decide how to plan, pay for, and ultimately build the service (Konvitz, 1985; Anderson, 1988). For example, the benefits of water and sewage treatment to health and economic development were well known by the middle nineteenth century, but it took US cities until 1940 to build such systems. World wide, hundreds of millions of urbanites live in political-economic environments that still

do not offer reliable water and healthy sewage systems, transportation systems, or power.

As such, the history of successful infrastructure investment is less about the direct impact of technology and more about the interaction between technology and society (Tarr, 1984). Put another way, recent scholars posit that infrastructure networks are both social and technical: they are always contested and their impacts on cities are never neutral (Graham, 2000). No matter how 'public' the good is perceived to be, the impacts of telecommunicative grids, transportation roads, and energy will always privilege some places and people over others (Swyngedouw, 1993).

Public Infrastructure Investment

However convoluted its investment process and uneven its impacts, infrastructure investment became essentially public practice in the twentieth century, carried out either by governments or heavily regulated private firms. Several reasons are offered for this (Neutze, 1997; Perry, 1995). First, urban infrastructure often serves the essential health and well-being of the citizenry, requiring full citizen access to such services at reasonable cost. Second, this implies the provision of goods at a scale and price (given the elasticity of demand of several of these services) that is beyond the capacity or interest of private providers. Third, urban infrastructure goods often constitute natural monopolies, whereby it is less costly to have a single provider than several service delivery systems. For example, it would be very costly to have competing water and sewer companies putting parallel networks of mains and pipes under every street in a city to give consumers a choice of systems. Fourth, some forms of urban infrastructure produce almost exclusively public goods or externalities (or services which can not be used by one consumer without also being made available to all), such as public roads, sidewalks, and parks. Fifth, equity can require that certain key benefits of urban infrastructure should not be withheld from any citizen. (Neutze, 1997: pp. 29–31)

Special Purpose Governments

Just as the conditions of scale, cost, and equity have led to public provision of physical infrastructure, the sheer size and the accompanying obligations of debt and delivery of infrastructure systems has often led one level of government (especially national governments) to offload many of these services on to lower levels of government. Municipal governments in turn have further devolved the delivery of infrastructure, one by one, to special purpose governments or public authorities (Sbragia, 1996; Perry, 1995). In the United States, for example, such governments issue the majority of all bonds used to finance infrastructure investment. It is argued that such decentralized structures work well to:

1. preserve and circumvent local and state debt limits, maintaining the legal requirements of general municipal fiscal balance while allowing special purpose, extra-municipal public agencies to generate debt, raise revenue, and build physical infrastructure networks; and
2. create more direct relationships between the government and the capital markets, thereby better satisfying market requirements for enhanced credit risk management (through municipal debt guarantees, or bond insurance, or policies of securitization, such as the provision of bank letters to offset credit exposure, etc.) in order to pay for infrastructure.

Critics of such public corporations point to their privatistic practices as evidence of the increasing transformation of government into 'business' (Walsh, 1978). Adherents suggest that the privatization of public infrastructure services in general and through special purpose governments and public authorities in particular is part of the century-long move away from the inefficiencies of the state and back to the private sector as the best, most stable source of infrastructure investment (Smith, 1999).

Infrastructure Investment as Public/Private Practice

In many ways, the dominant normative consideration of public infrastructure investment has come full circle, with a twist. Where conditions of scale and cost, and developmental importance made infrastructure investment essentially a public or governmental function at the beginning of the twentieth century, the very same issues are challenging the capacities of the state and forcing new mixes of public and private service delivery at the beginning of the twenty-first century. The government, at national and local levels, is finding it difficult to fully conceive, finance, build, or efficiently maintain modern systems of urban infrastructure. This is held to be equally true for basic infrastructure systems in the emerging urban centers of the developing world (Smith, 1999) and for advanced telematic systems of telecommunication and digital media that are radically transforming the space of urban flows in general (Graham and Marvin, 1996).

Emerging Cites in an Urban World

Nowhere are these arguments more forcefully made than in the literature on infrastructure development in emerging cities. Increasing patterns of economic globalization and migration into cities are central features of global geographic and social development. Sometime in the last decade of the twentieth century, the world became 'urban,' more than 50% of the global population could be found living in towns and cities. The emerging cities of this new urban world face tremendous infrastructural challenges with limited technological and fiscal resources, and yet they represent stable and viable places to ever more people (Clark, 1996).

Just as issues of health, transportation, and scale challenged the United States and Europe at the beginning of the twentieth century, similar patterns, at an even greater scale, challenge the emerging urban centers of Latin American, Asia, and Africa in this century. Millions continue to move to the cities without access to basic infrastructure facilities such as safe water, sanitation, and garbage disposal.

Financial Practices: A Public–Private Mix

While national governments remain the single most important source of infrastructure delivery in the emerging urban world, the costs, which can be as high as 10% of GNP, suggest

that they cannot do it alone. They must attract domestic and international equity capital for private investments in the infrastructure. This requires the move to Western-style financing schemes and patterns of governmental devolution of infrastructure investment, making it a more 'public–private' activity worldwide.

In the past, municipalities (especially in developing countries) were able to combine their own taxes with central government transfers to build public works, but now infrastructure demands make them just as fiscally burdened as their national governments. In addition, they are required by both the national government and international banks to 'forge partnerships with financiers, private operators and constituents' (El Daher, 1997: p. 1). The sources of revenue available to governments to pay for such services generally fall into three categories: (1) taxes, (2) user fees, and (3) other forms of leases (and purchase agreements) and revenue schemes. Depending on their success in using these sources of revenue, cities' infrastructure investments require the organization and constitution of government to accommodate new debt structures, create relationships with the capital markets, and regulate public–private infrastructure agreements. In certain key areas, the infrastructure investment is becoming even more privatized or transferred to the private sector through deregulation, concessions, contracting out, and private management and control agreements.

Access to Private Investment Markets

Considering all of this, a most important signifier of infrastructure investment in cities is their access to the credit markets, that is providing the institutional transparency, strong government regulatory power, debt guarantees, and revenues needed to secure an attractive private investment climate in which to develop infrastructure. While these are common issues of municipal infrastructure finance everywhere in the urban world, in no places are they any more evident than in developing countries where not only can the fiscal strength of the municipality be open to question, but also the very existence of a stable viable domestic credit market can be equally problematic. Cities in developing countries often have more success generating direct private investment in fully privatized public works than in creating the stability of process required of a local municipal bond market.

In a rapidly urbanizing world and uneven investment climate, nongovernmental intermediaries like the World Bank, the IMF, the Inter-American Development Bank, and the Asian Development Bank have become important sources of infrastructure investment policy. They attempt to provide debt guarantee instruments and policy strictures designed to influence the creation of stable domestic capital entities, with the larger purposes of not only institutionalizing long-term markets but also enhancing governmental legitimacy across regimes.

Infrastructure Investment and Urban Development

Infrastructure investment is an important way to view the urban. It represents networks of technology and urban life, binding them together in patterns that are clearly important elements of cities and their development. It comprises a substantial share of the sunk physical capital of cities; materially delivering the networks of heat, light, water, telematics, and power that are central to urban life; without them modern cities do not exist (Graham, 2000: p. 115). The material grids of such components of the urban landscape and their accessibility go a long way toward explaining what is meant by the 'developed' and 'developing' urban world.

The study of infrastructure investment provides an understanding of the state as a site of debt and public regulation and the market as a site of capital and risk-generated requirement. The restructuring of the market into risk niches and intermediaries and the state into devolving agencies of delivery and transfer in both developed and developing urban centers are central characteristics of infrastructure investment as a public-private practice of the new urban world. More generally, the full implementation of infrastructure investment is a key element of the dominant practices of urban political economy: the structuring of government, the creation and regulation of capital markets, the conditions of uneven urban economic development, and the socio-technical networks of service and underservice that represent the distributions of power in the city and globally (Tarr, 1984; Swyngedouw, 1993). In sum, the study of infrastructure investment is the study of urban development.

Abstract

The concept of infrastructure refers to the embedded, often invisible technical support structures that help to deliver services to a population or organization, most commonly water, energy, and information. Infrastructures mediate human interaction and shape social organization. Anthropology has developed a relational perspective on infrastructures analyzing them as the ongoing interweaving of embodied social and political choices, moral orders, and technical networks. This approach has much to offer for anthropologists, because it is largely based on ethnographic research, shows a deep commitment to materiality as practice and provides a productive way of thinking through the changing relations of center and periphery. It is an area of research with important intersections into the information sciences and urban studies.

Introduction

There exist a number of topics within anthropology that for long stretches within the history of the discipline, and somewhat surprisingly, suffered the fate of "handmaiden to other anthropological frames and issues" (Munn, 1992, p. 93). Infrastructure is one of them, the body is another. It is as if their ubiquity, the fact that they "[mediate] all reflection and action upon the world" (Lock, 1993, p. 133), renders them moot and implicit in anthropological inquiry. The concept of infrastructure refers first and foremost to modern technical structures such as roads, power lines, or databases that support particular forms of work and social life. Much of anthropological research, however, has taken place in settings where perhaps technical infrastructures did not play a particularly central role in the organization of social life. And where they did, anthropology, for a long time, was not particularly interested in analytically foregrounding material culture and technical artifacts as infrastructure in the modern sense. Hence, the Azande's grain storage vessels featured centrally in Evans-Pritchard's ethnography and his analysis of forms of rational explanation. Yet they were not problematized as part of a technical supply infrastructure that may be implicated in shaping those forms of rational explanation. Infrastructure as an analytical concept in anthropology has thus largely lain dormant until the late 1980s, when research at the interface of ethnomethodology, anthropology, feminist critique, and science and technology studies showed that infrastructure was not simply a technical artifact that supported social life. Rather, infrastructure mediated and shaped social practice (Star and Ruhleder, 1996). This perspective opened infrastructure up as an anthropologically useful concept to think through aspects of the relational work that goes into human interaction and that helps to configure social organization. It has made infrastructure accessible to social and cultural inquiry along new analytic paths, paths that research until then, which had treated infrastructure largely as an object, had not been able to cleave. Neither the structural Marxist analyses of the material basis of the social relations of production nor the detailed attention of the engineers and planners in charge of constructing and maintaining infrastructure as a technical object, turned the concept of infrastructure into one that anthropologists would find particularly useful to think with and to invent around. Today, infrastructure as part of an increasingly relational and practice-oriented thinking is rapidly becoming a well-established topic of anthropological research, particularly at the intersections of sociocultural anthropology, and science and technology studies with important alliances into the information sciences and urban studies.

This article deals with the analytical, epistemological, and methodological issues that have arisen during research on infrastructure since the 1990s charting genealogies where appropriate. The emphasis is on the new and productive ways in which infrastructure has been problematized (Rabinow, 2003). Infrastructure refers to the embedded, often invisible technical support structures that help to deliver services to a population or organization, most commonly water, energy, and information. Yet, these technical support structures are now conceptualized relationally as transient embodiments of social, technical, political, economic, and ethical choices that are building up incrementally over time. Analyzing infrastructure as part of an ecology of infrastructure thus offers a way for the social sciences to inquire into human interaction and social organization, a way that emphasizes the partial connections between structure and agency, and inquires into the 'how' of connecting and its implications. This thought style has much to offer for anthropologists, because it is largely based on ethnographic research, shows a deep commitment to materiality as practice and provides a productive way of thinking through the changing relations of center and periphery.

The article is divided into three core sections. Section Analytical Uses discusses three analytical uses of the concept of infrastructure: ecologies of infrastructure, dys-appearing infrastructure, and infrastructure and statecraft. These are heuristic distinctions that reflect three uses of the concept of infrastructure that are very much aware of and borrow from each other. Section Epistemological Issues discusses epistemological issues arising in and from infra-structural research, most importantly the shift from

infrastructure to infrastructuring. Section Methodological Issues raises a number of methodological points that pertain to research on infrastructuring and that inform a wider debate about the changing practices of ethnography as method.

Infrastructure: Analytical Uses

Ecologies of Infrastructure

Infrastructure is crucial for social organization yet often invisible, physically as well as in social scientific or public discourse. This discrepancy marks the starting point for the research on ecologies of infrastructure that has brought together anthropology, science, and technology studies; history; and information science, and that has been advanced primarily through a focus on informational infrastructures supporting organizations (Bowker and Star, 1999). Ecological infrastructure research has initially developed from the analysis of standards and classifications as practices connecting formal knowledge, social interaction, and organizational structure (Bowker and Star, 1999; Star and Ruhleder, 1996). This thinking evolved into a relational view of infrastructure as a continuous coordinated networking of social organization, moral order, and interweaving layers of technical integration. It refuses to reduce infrastructure to the status of technical object. Following Bateson's argument that one can only ever study relationships and never a 'thing,' ecological research on infrastructure is interested in the manifold relations between technical structure, routines of work, wider scale organizational and technical resources, as well as heterogeneous communities of users – relations always understood as continuously enacted in everyday practice stabilizing a particular albeit contingent, negotiated order (Bowker and Star, 1999; Law, 1994).

Infrastructure seeps into the background, it sediments out and disappears from view. And with it disappear all the technical, social, political, and ethical choices that are necessarily made during the design, construction, implementation and maintenance of any infrastructure. "[Down-stream], the choices made in the building of the […] systems may no longer be obvious or even visible to ordinary users. The civics retreats silently into the infrastructure" (Fischer, 2005). Hence "[u]nderstanding the nature of infrastructural work involves unfolding the political, ethical, and social choices that have been made throughout its development" (Bowker et al., 2010, p. 99) and that often appear at the surface as mere technical decisions.

Born out of this ecological perspective, the following criteria have been established to define infrastructure (abridged from: Star and Ruhleder, 1996, p. 34):

- Embeddedness: Infrastructure is sunk into other structures, social arrangements, and technologies.
- Transparency: Infrastructure does not have to be reinvented each time or assembled for each task.
- Reach: Infrastructure has a temporal or spatial reach beyond a single event or one-site practice.
- Learned as part of membership: The taken-for-grantedness of infrastructure is a *sine qua non* of membership in a community of practice. Strangers and outsiders encounter infrastructure as a target object to be learned about.
- Links with conventions of practice: Infrastructure both shapes and is shaped by the conventions of a community of practice.
- Embodiment of standards: Infrastructure plugs into other infrastructures and tools in a standardized fashion.
- Built on an installed base: Infrastructure does not grow *de novo*; it wrestles with the inertia of the installed base and inherits strengths and limitations from that base.
- Becomes visible upon breakdown: The normally invisible quality of working infrastructure becomes visible when it breaks down.
- Is fixed in modular increments, not all at once or globally. Infrastructure is big, layered, and complex, and hence never changed from above. Changes take time, negotiation, and adjustments.

These criteria are sufficiently generic so as to be applicable to almost any type of infrastructure. They have been widely employed in social scientific research, predominantly in the areas of computer-supported cooperative work and learning environments, ubiquitous computing, and technically mediated forms of health care practices. Recent ethnographic research in this vein reaches from infrastructures of governance and administration in mental health care to urban utilities in the Global South (e.g., Levinson, 2010; Mcfarlane, 2011). More recently, the interest has expanded toward cyber infrastructures (cf Bowker et al., 2010) in domains of knowledge making that have traditionally relied less heavily on technical artifacts, particular the humanities, and in fields that have rapidly risen from local endeavors to truly global networks such as the climate sciences and molecular biology.

Infrastructures build up over time and form layers. It is this temporal dimension of infrastructure, which has interested historians of science in large-scale systems and their infrastructures. Their analyses demonstrate how infrastructures are seldom mere technical solutions to a societal need or want. "We see things and name things differently under different infrastructural regimes" (Star, 1999). Infrastructures mediate the looping between naming and 'ways to be a person' thus shaping how people are moving targets (Hacking, 2006). "Infrastructure does more than make work easier, faster or, more efficient; it changes the very nature of what is understood by work" (Bowker et al., 2010, p. 108). And as the following section will show, it is not only work. Infrastructuring often has more far reaching and existential implications. It is heavily implicated in shaping the very nature of life, labor, and language (Foucault, 1970).

Dys-Appearing Infrastructures

An important strand in anthropology is interested in the 'dys-appearing' of infrastructure (Akrich and Pasveer, 2004). Infrastructure comes to matter in its failing: as acute or chronic infrastructure failure denying access to and fair and equal distribution of the basic means of living. Infrastructure only becomes visible, present, and experienced in its failure to deliver what has been promised by authorities, by development agencies or by narratives of modernity.

This thinking is deeply embedded in the history of anthropology. It has its roots in Marxist historical materialism, translated primarily through the writings of Althusser and Gramsci into the structural Marxism of anthropology in the 1970s, cleansed of its structuralist underpinnings by Bourdieu and particularly Foucault in the 1980s, before opening out into a rich delta of approaches integrating elements of feminist and postcolonial thinking and developing a strong interest in spatial and ecological thinking, particularly in urban studies. The original understanding of infrastructure within this Marxist tradition has been discussed controversially and this is not the place to begin to unravel its complicated genealogy (cf Godelier, 1978). Suffice to say that infrastructure has primarily been discussed as part of the trias superstructure, infrastructure, and ideology, with infrastructure initially understood to be the tangible and material setting within which class struggle needed to operate. Other proponents have conceptualized the differences between super- and infrastructure in terms of function rather than institution. Infrastructure in these terms becomes one particular social form of production analytically integrating elements of the local ecosystem, productive forces, and social relations of production, and in this almost ecological sense forming the place of class struggle. While there is a chronology to these different readings of infrastructure within anthropology, they certainly do not follow each other in evolutionary succession. Rather, the different readings exist side by side emphasizing different analytical and political concerns.

What unites these different readings of infrastructure is the primary concern with processes of subjectivation or interpellation rather than infrastructure per se. What differentiates them is whether they understand this process of making a subject as a process driven by ideology (structural Marxism, Gramsci), by the micropolitics of power/knowledge (post-structuralism, Foucault) or mediated through ecologies of infrastructure (science and technology studies, Star). Empirically, structuralist approaches display a strong tendency to investigate infrastructure as a technical object and a black box. Not its everyday working practices are of interest, but the fact that it historically embodies ideology and thus materially determines the (re)production of an unjust set of relations of production and exchange. Foucault has turned structuralism on its feet concerning himself with the conditions for the emergence of an apparatus, i.e., the physical, administrative and epistemic mechanisms of power. This approach treats infrastructure still as an object, but with an interest in how that object is engaging in forging relations. The concern lies with the mechanisms through which infrastructure as a technical object makes certain connections and denies others, thereby mediating the micropolitics of power/knowledge. This relational thinking paves the way for the last shift, driven primarily by the social construction of technology and material-semiotics: technical infrastructure is drawn into the mangle of practice (Pickering, 1995). Infrastructuring as a material-semiotic practice makes infrastructure available to cultural analysis not only as an object or the carrier of ideology but as a socio-technical phenomenon and practice relating technology, actors, and moral orders in specific ways. Infrastructure ceases to be a black-boxed technical object. It is pried open by practice-theoretical, constructivist inquiry revealing the ongoing work that goes into making it into a seemingly stable, technical object. The sharp Marxist distinction between subject and object, which Foucault already problematized when analyzing technologies of the self as relational manifestations of power, is dissolved altogether in the mangle of practice. This does not mean that research on ecologies of infrastructure is not concerned with interpellation and the making of subjects any longer. Yet interpellation as a matter of practice is not about subjects and objects, where subjects are made and objects are invariant contributors to this process. Rather interpellating as an everyday practice mangles subjects and objects, constantly changing roles, perspectives, and agencies thus rendering the distinction meaningless. Water pipes are objects of design practices one moment and defective agents in water delivery in the next. Utility infrastructuring as a material-semiotic practice thus interpellates 'life as such' (Fassin, 2009), because it embodies and enacts political and ethical choices and helps to shape the "quotidian practices and […] 'microspheres of negotiation' through which [people access resources]" (Gandy, 2008, p. 125).

Infrastructure does not only dys-appear for those marginalized and in the periphery. Infrastructuring instead focuses one's attention on the partial connections between center and periphery (Hannerz, 2001). Infrastructure is commonly designed in the center and here it dys-appears in the design and construction process. Struggles arise over defining the problem that infrastructure is meant to solve, over aligning and legitimizing inevitable sociotechnical choices, and overdealing with uncertainty and ambiguity in long-term planning processes. Yet infrastructure dys-appears in the center always in relation to a representation of the site of its deployment, i.e., some idea of the periphery. In the periphery itself, infrastructure dys-appears differently. It dys-appears because it does not deliver what is needed. It breaks down, it has unintended consequences and side effects, and it is appropriated in ways that change its original intent for better or worse or infrastructure does what the center intended, but that is not what anyone in the periphery wanted or needed. Yet these forms of dys-appearing also relate to design and construction choices made in the center. Infrastructuring then focuses the analytical attention on the partial connections between center and periphery, on the way one sees the other, on the exchanges, connections, collisions, and dependencies between center and periphery on different spatial and temporal scales. In fact, center and periphery only take shape the way they do and for the moments they do, because they are partially connected through processes of infrastructuring in specific ways.

Most of the anthropological research in this trajectory of dys-appearing is concerned with utility infrastructure in the major metropolitan regions in the North and South and convincingly demonstrates just how central infrastructure is "in the construction of the city as 'modern', as a site of capitalist production and expansion, as constitutive of social relations of inequality, and as a space of environmental transformation" (Mcfarlane and Rutherford, 2008). To a degree, this strand of research remains true to its Marxist roots with a continued interest in the hidden materialized networks of fetishized relations of production and demonstrating the instrumental role of infrastructure in mediating power relations. Many recent analyses in this vein oscillate between foregrounding

the political, ethical, and economic choices that go into infrastructure design and operation on the one hand, and on the other hand, the tactics, appropriations, and suffering of those living with the effects of these choices. They oscillate between narratives of top-down power and the manifold resistances against it that are always also articulated in material, i.e., infrastructural terms.

Inspired by the watchful critique of the consequences of increasingly global flows of people, things and knowledge (Appadurai, 1991; Hannerz, 1997), the notion of the assemblage (Collier and Ong, 2005) has advanced a more ecological understanding of infrastructure: "'Infrastructure' designates specific institutional, material, or social conditions through which the functioning of a certain technology, ethical regime, form of regulation, or mode of communication is either enabled or impeded. It inscribes the space and form of limited, finite, and localizable relationships and effects that occupy a certain space and that concretely link – or distinguish and divide – various objects, spaces, techniques, individuals" (Collier and Ong, 2003). This definition firmly establishes infrastructure as a coconstitutive part of cities as urban assemblages and extends the concept from its traditional focus on utilities to include

- the political and media infrastructures, i.e., means and modes of representation, and how they contribute to an infrastructure politics;
- people as infrastructure in constellations where the material and technological means are minimal and forming support networks and communities becomes the most important resource; and
- the emergent informational infrastructures that are rapidly changing from top-down service provision to ubiquitous and increasingly user-generated networks of communication and interaction.

Ubiquitous computing, sensing technologies, cartographic techniques, and manifold forms of 'urban hacking' are rapidly developing into a pervasive information infrastructure woven into the urban fabric and they are involved in reconfiguring modes of representation and participation in processes of infrastructure development and distribution.

Infrastructure and Statecraft

The governance of and control over infrastructure has always been a crucial technique of modern government. In the longue durée of infrastructure development, infrastructure is an integral part of the architectures of modernity, be it as an element of nation-state formation, of countless efforts of modern state governments to impose a singular order on society, or as an element in late modern attempts at governing increasingly complex urban fabrics. The art of governing in modern societies has always depended on "'geopolitics', whereby the state uses technological means to transform the land into both a resource for administration and a symbol" (Mukerji, 1994). If controlling infrastructure is an important technique and strategy of rendering a society governable, it is of little surprise that movements of resistance struggle to (re)gain some control of infrastructures, most recently information infrastructures in movements of political change in North Africa and the Middle East (e.g., Fischer, 2010). Less immediately visible, because it is operating at a much larger temporal and spatial scale, is the intense link between utility infrastructures and the flows of political and economic power at large. The notion of carbon democracy (Mitchell, 2009) focuses historical attention on how the histories of carbon-based fuels, i.e., coal and oil, and Western politics and statecraft are closely aligned throughout the twentieth century. The concentration and control of energy flows shapes democratic possibilities and, during the postwar period, democratic stability and its implicit goal, the growth of markets, have become closely aligned with the circulation of fossil fuels and hence infrastructure and infrastructural decisions.

In anthropology, this historical analysis has been extended into the ethnographic present to investigate energopolitics, i.e., the power over and through energy, in an analogy to bio- and geopolitics (Boyer, 2011). "[…] Power over energy has been the companion and collaborator of modern power over life and population from the beginning" (Boyer, 2011). Particularly as countries all over the world are beginning to face up to the transition to renewable energy sources, existing infrastructures need to be extended or replaced in major national efforts requiring a plethora of political, technical, economic, social, and ethical choices. The transition into renewable energies requires careful infrastructuring in a political and economic field that is dominated by major industrial actors; a technological field that has not settled on key technologies yet and that is still witnessing a multitude of decentralized, often very local initiatives and innovations; and a civil society particularly in the affluent North that so far shows little inclination to reduce energy use or develop other ways of accounting for its externalities. It is an important task of infrastructure research as part of an anthropology of the contemporary to analyze these processes of energy infrastructuring and understand and make visible the social and ethical implications of choices that are often made as technical choices in the here and now but that have significant global consequences far beyond the present.

Infrastructure: Epistemological Issues

Ecological infrastructure research begun to develop in the 1980s, a time in anthropology when important theoretical advances were made through feminist critique, a heightened sense of reflexivity, and the integration of scientific and technological practices into cultural analyses. It is in this intellectual environment that infrastructure ceases to be a technical object or material repository of social and cultural activity. Infrastructure becomes part of material-semiotic practices (Haraway and Jeanne, 1991) and hence part of cultural analysis in very much the same way that science and its laboratories were coming to be understood as intimately and inextricably woven into the fabrics of modern societies (Martin, 1998). Infrastructure becomes legible through the analytical lens of culture; it becomes anthropological strangeness of a second-order, "that of the forgotten, the background, the frozen in place" (Star, 1999, p. 379).

The ecological and relational perspective grants infrastructure a more active role in contributing to material-semiotic

practices. This shift in perspective allows the analysis to take into account that infrastructure never really works the way designers intend. Infrastructure always 'does' unintended and unforeseeable things and it has to be able to do so. Infrastructure is never simply rolled out into everyday life as the term infrastructure implementation suggests. It needs sufficient degrees of freedom to accommodate the heterogeneity and dynamics of social practices. The fit between plan, infrastructure and social practices needs to be produced and continuously reproduced in situated action (Suchman, 1987) and in careful tinkering (Mol et al., 2010). Hence, infrastructure is not any longer passive repository of a homogeneous culture waiting for an anthropologist to take a reading. It is part of material-semiotic practices and is analyzed in its ability to help or hinder the forging of relations. It is analyzed in its ability to stabilize particular configurations, i.e., its ability to shape culture as practice.

Infrastructure in an ecological reading ceases to be a homogeneous technical artifact. Rather it is understood as a fluid technology contributing to practices in multiple ways. Deleuze captures this new sense when writing about the device: "[a multi-linear ensemble] composed of different sorts of lines. And these lines do not frame systems that would be homogenous as such (e.g. the object, the subject, the language). Instead, they follow directions, they trace processes that are always at disequilibrium, sometimes coming close to each other and sometimes getting distant from each other. Each line is broken, is subjected to variations in direction, bifurcating and splitting, subjected to derivations" (cited in Muniesa et al., 2007). It is in this sense that the shift is introduced from infrastructure as a noun to infrastructuring as a verb and as an ongoing practice: "Discussing 'infrastructure' as a noun […] suppresses the variety of material and non-material components of which it consists, the efforts required for their integration, and the ongoing work required to maintain it" (Bossen and Markussen, 2010). Hence, the shift from infrastructure to infrastructuring is not only a methodological shift toward the analysis of infrastructure in the making. It is also an epistemological shift toward infrastructuring as articulation work entangling actors, technologies, and moral orders in specific ways. Infrastructuring is never simply the design and bringing into being of a technical artifact but it is an ongoing attempt at ordering social practices, an engagement in heterogeneous engineering (Law, 1994).

Infrastructure: Methodological Issues

Inversion and Othering

This final section discusses briefly three methodological issues that arise in the context of infrastructural research: infrastructural inversion and othering, relationality as an ethnographic challenge and infrastructure as an ethnographic resource. In the late 1980s, the history of science began to analyze large-scale systems as emergent sociotechnical networks concentrating for the first time on infrastructure and technology rather than the people and ideas these were supposed to enable and advance. Bowker (1994) referred to this shift in focus as 'infrastructural inversion.' Practicing infrastructural inversion means turning figure into ground and vice versa and investigating not an object but relations (Bowker et al., 2010). Particularly in the history of science, this is a powerful methodological shift that puts the emphasis firmly on sociotechnical networks in the making as well as the choices and path dependencies that channel these developments. Yet there is a larger point to figure and ground reversals that anthropology has raised and that is relevant to the analysis of infrastructuring. Marilyn Strathern points out that figure and ground do not relate to each other in a part–whole relationship constituting some kind of totality. "Figure and ground work as two dimensions. They are self-scaling – not two perspectives as it were, but a perspective seen twice, ground as another figure, figure as another ground. Since each behaves as an invariant in relation to the other, the dimensions are not constituted in any totalising way" (Strathern, 1991, pp. 112–113). One important methodological implication is that the ethnographer may try to oscillate between perspectives and attempt different kinds of involvement in the field. Key to such an approach, however, is not the integration of different analyses into a coherent whole, but rather to explore how they relate to each other, always only partially connected, and how the constant failure of any perspective to capture something whole and complete, starts to produce something interesting when put next to other failures.

The analysis of the literature on infrastructure not only in anthropology shows that each discipline names and treats as infrastructure (ground) that which is not its research object (figure). Thus, the social and cultural sciences interested in social organization and human interaction frame the technical environment of particular situations as (technical) infrastructure. The computing and engineering sciences primarily interested in the coordination of technology and algorithms make social interaction their (social) infrastructure. Thus, disciplinary thinking runs the risk of not seeing figure and ground as partially connected but of othering the ground by keeping it invariant, black boxed, and detached from the analysis. Already in 1935, Ludwik Fleck demonstrated how the philosophizing naturalists of the early twentieth century, e.g., the Vienna Circle, saw facts as variable and human thought and logic as fixed, whereas humanist philosophers thought of facts as fixed and of human thought as variable: "It is characteristic that both parties relegate that which is fixed to the region with which they are unfamiliar" (Fleck, 1935/1979, p. 50).

Relationality and Different Modes of Infrastructural Research

The particularly modern epistemological split in attention to either matter or meaning that Fleck points out continues throughout the better part of the twentieth century and is now increasingly dissolved in relational infrastructure research. Researching infrastructure today always attempts to relate three analytical dimensions to each other: "ubiquity, material and semiotic (texture), indeterminacy of the past (identity politics), practical politics of designing infrastructures (how to do it and the (in)visibilities it produces)" (Star, 1999). Relating these dimensions to each other and exploring the connections between them forces anthropologists to continuously cross established modern boundaries of matter and meaning and of disciplinary thought. Anthropological research on infrastructuring thus not only becomes an inherently

transdisciplinary endeavor. It also challenges in different ways the ethnographic method.

First, new models for 'scalable qualitative research' (Bowker et al., 2010) are called for, i.e., the variance in the phenomena being studied ought to be matched by the variance in the size of research teams. While there are many very good reasons for individual fieldwork in many cases, there are equally good reasons in the case of infrastructure phenomena that argue for larger teams able to match the heterogeneity and scale of infrastructure. Infrastructures are often distributed across large spaces, they span center–periphery relationships and they connect many different places. There is also a temporal dimension: changes somewhere in the network may have effects in several other locations at the same time. The spatial distribution and simultaneity of infrastructural phenomena challenges the revered ethnographic principle of co-located i-witnessing.

Second, understanding infrastructural phenomena as material-semiotic practices requires multimodal research (Bowker et al., 2010), i.e., diversity in methods and methodologies each with their own strengths and weaknesses. And it requires analytic means of relating the different outputs together: thick descriptions, narratives, technical data, and maps. These cannot be triangulated in any simple sense to achieve a more comprehensive understanding of the phenomenon. Rather the interesting findings come from understanding how different results partially connect to each other.

Last, new ways of knowing are required if the different methods are not to produce segregated analyses of the social, organizational, technical, and cognitive aspects of infrastructure as if these were somehow sitting on top of and apart from each other and not entangled in highly specific ways. The established textual form of the ethnography has long ceased to be a singular and monolithic narrative. Experiments with perspective, coproduction, and style are widespread. Research on infrastructure encourages anthropology to carry these experiments further into distributed and only partially connected ways of knowing.

Infrastructure as Ethnographic Resource

Another challenge to the co-location of ethnography comes from the 'intimate sciences' such as the humanities (Beaulieu, 2010), where knowledge practices are often difficult to engage ethnographically as they are private and individualized rather than collective and publicly displayed, for example, in laboratories. While Wittgenstein alerted not only anthropology to the fact that language and thinking are also embodied practices, this remains difficult to translate into ethnographic research, not because it is an epistemological impossibility to observe thinking practices, but because most people for many good reasons want to be left alone when thinking. Despite this apparent need for privacy, or maybe because of it, cyber infrastructures are playing an increasingly important role in the humanities strengthening networked knowledge practices. These infrastructures can also be conceived of as a resource for ethnographic research as they offer the possibility to create a co-presence of the ethnographer with the research community in question without requiring co-location. Ethnographic copresence has to do with the alignment of observing and observed practices through information infrastructures, sharing channels of communication; of data management; and of reflexive commentary. It offers possibilities to partake in the practices of knowledge production in asynchronous ways and at a physical distance without being detached. It offers more co-laborative roles to the ethnographer than passive observer, including author, participant, and scholar. The multisitedness of the traveling individual becomes here not a matter of sequential co-location, but of interaction distributed along information infrastructures such as mailing lists, Web sites, or databases.

In-House Counsel

Robert E Rosen, School of Law, University of Miami, Coral Gables, FL, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

In-house counsel refers to professionally trained employees working for an organization's law department. They may not be the only legally trained individuals working for the organization, nor the only employees responsible for the legal work of the organization. They are defined by working in a legal department and reporting to a chief legal officer/general counsel. Sociological research on in-house counsel has focused on in-house counsel being both organizational and professional actors.

In-house counsel are legally trained employees who have responsibilities for some of the law jobs of the organizations employing them. The phrase 'legally trained' does not necessarily mean 'lawyer' or 'attorney,' as in some parts of the world paralegals or notaries hold these positions too. Organizations having needs for legal services may resolve them internally by employing those externally trained in the law or by allocating authority over law jobs to those who did not externally receive legal training (Llewellyn, 1930; Abbott, 1988). Organizations also can resolve their legal needs externally. There is a market of vendors offering to help businesses meet their legal needs, most notably law firms who serve as 'outside counsel.' From a professional perspective, the choice between an in-house (or inside) counsel and outside counsel is simply a 'make or buy' (Williamson, 1975) business choice (Schwarcz, 2008), but it is a choice that takes place in the presence of conflicts over business prerogatives, professional privilege, and regulatory legitimacy.

Delimiting the Role of In-House Counsel

Many individuals with external legal training work for organizations in other than distinctly legal capacities. In most of the world, university legal study usually does not lead graduates into careers as legal professionals (Twining, 1994). These graduates take a facility in the law into whatever positions they assume. Others may leave a career in law to work for organizations in positions other than that of in-house counsel (Rosen, 2002a). The jobs performed by legally trained employees inside corporations are not coextensive with law-related jobs.

In some countries, including the United States, lawyers may combine being lawyers with careers as organizational actors. Legally trained executives thus may be subject to professional sanction even when they are not in-house counsel. This allows the professional association to sanction lawyers for their organizational activities (see, e.g., In re Nixon, 1976) (disbarment of Richard Nixon for his actions not as a lawyer, but as U.S. President), theoretically encouraging lawyers to act as organizational gatekeepers. On the other hand, corporations can claim benefits – primarily the ability to assert the professional privilege to keep communications confidential – because they have chosen to hire a member of the legal profession (DeStefano, 2009). In most of the world, however, the professional privilege is much more constrained (see, e.g., Akzo Nobel, ECJ, 2010), as are the professional responsibilities of lawyers when they are not acting before a court (Van Houtte, 1999) (European countries).

In-house counsel are not distinguished from other law-trained employees simply because they are primarily employed for their law training and practice experience. Corporate finance departments, for example, may employ law graduates, some with significant careers as lawyers, to perform law work. These individuals, however, have not been considered to be in-house counsel. Although they perform legal work and are law graduates, they report to the corporate finance department, not to the organization's general counsel. An organization's *law department*, managed by the chief legal officer/general counsel, gives birth to and is the home of in-house counsel.

Legal work is performed in organizations also by those who are neither legally trained nor part of the legal department. Executives, staff members, regulatory specialists, managers, and salespeople may be responsible for a number of law jobs. Non-legally trained employees, for example, may negotiate, write, and sign contracts. Organizations also may have such continuing relations with regulators that they develop specialized subunits, separate from the legal department, such as employment or environmental relations offices, with responsibilities for legal compliance and dispute resolution.

There are many professions that compete with the legal one to supply businesses with legal services. Human resources is one such group (Edelman, 1990). The movement of work into the legal department indicates a victory for the legal profession, a recognition of its jurisdictional claims. But work may leave the legal department too; at the time of writing this article, for example, many compliance departments in the United States are emerging in response to new legal regulations that demand compliance activities. These compliance departments may be staffed by non-lawyers.

In sum, with in-house counsel organizations delimit a distinctly legal capability, but in-house counsel's responsibilities are neither coextensive with the organization's law jobs nor comprehensive of organizational law compliance. Legal departments and their employed lawyers provide the organization with a professionally managed legal capability (Mackie, 1989). The scope of the work allocated to the legal department,

 http://dx.doi.org/10.1016/B978-0-08-097086-8.86016-X

and consequently the work delimited to inside counsel, depends importantly on the legal regime and its professionalization and regulation projects.

Whereas in the past, "[e]very country had its own formal and informal understandings about what it means to be a lawyer and how law should be practiced, … in an increasingly interdependent world, these norms inevitably come into contact" (Wilkins, 2012: p. 275) and are subject to hegemonic market forces. Thus, there may be emerging from the centers of finance a general understanding of the roles to be played by in-house counsel (Wilkins and Papa, 2013).

In-House Counsel as Organizational Actors

In-house counsel vary in their work responsibilities. Some organizations make in-house counsel rather than buying their legal services across the market to increase the efficient delivery of recurrent predictable legal work. Others may hire in-house counsel because firm-specific knowledge is needed to provide rather routine legal services. Others may hire in-house counsel in imitation of other organizations. Still others risk reducing organizational flexibility and hire in-house counsel to increase the organization's coordination and control of its legal services (Chayes and Chayes, 1985).

The extent to which in-house counsel assume organizational responsibilities has varied greatly (*compare* Miyazawa, 1986 on Japanese corporations in the United States *with* Rosen, 2010b(1984) on California corporations). In-house counsel perform a staff function, but, either individually or organizationally, they also may command executive power. In-house counsel may extend beyond fulfilling a staff function by making professional jurisdictional claims, for example, by demanding and gaining a voice in the choice of remedy for legal problems. In-house counsel also may extend beyond fulfilling a staff function on the basis of personal qualities of the lawyer or a demonstrated history of knowing what the organization needs.

In the United States, in-house counsel make professional claims to organizational power. The rules of the legal profession require in-house counsel and legal departments to have access to the Board of Directors (ABA, Rule 1.13). Some in-house counsel secure these organizational powers by emphasizing their skills in handling legal risk. Others do so by emphasizing their knowledge of the risk levels of the corporate cultures. In exercising executive power, in-house counsel decide or help decide for the corporation. Some in-house counsel, formally or informally, become company managers at the same time as they are members of the legal department. In the United States, organizations 'professionalize' themselves by hiring in-house counsel (Parker, 2010).

Consistent with the success of the law's professionalization project, in the United States, it is not unusual for legal training and practice experience to lead individuals to executive positions in corporations. But whether the CEO holds a JD also depends on how the organization perceives the importance of regulatory compliance, the prerogative of business norms, and competition with employees from other disciplines, such as finance (Rosen, 2002b).

Today, in the U.S. business sector, many in-house counsel are involved in compliance issues and other strategic decisions that gain them access to the ultimate organizational decision-makers. U.S. in-house counsel have won the right to monitor and review legal services produced in departments other than the law department as well as that purchased across the market and produced by outside counsel. Often, in-house counsel even are sought for their judgment about decisions where legal risks do not predominate (Rosen, 1989).

In many other economies, corporate in-house counsel less frequently are ceded executive responsibility (see, e.g., Van Houtte, 1999; Daly, 1997). In many places in the business world today, in-house corporate counsel resembles U.S. corporate counsel of an earlier era. Although situations varied depending on the trust and confidence particular in-house counsel attained, in-house counsel used to perform only scrivener and secretarial tasks, carrying out decisions reached without their significant input (Rosen, 1989). But even in economies where in-house counsel have few responsibilities, global corporations located there use in-house counsel more in line with the U.S. model (Daly, 1997).

David Wilkins outlines strong forces leading toward the export of the U.S. model of in-house counsel (Wilkins, 2012). In the United Kingdom, this has already occurred (Sako, 2011). Foreign direct investment, with its attendant knowledge and capital flows, is fostering this export to other countries. Among the BRICS countries (Brazil, Russia, India, China, and South Africa), Wilkins and his team find the increasing export of the U.S. in-house counsel model, everywhere but Russia. Wilkins' findings are consistent with Hendley's findings in the late 1990s (Hendley et al., 2001; Hendley, 2010) that Russian in-house counsel did low-level work, had a marginal position in the company, and were reluctant to exercise even the most obvious gatekeeping function. Whether these findings are still representative, however, can be questioned (see Martindale-Hubbell, 2009). As Liu notes, the role of lawyers and the legal profession are moving targets and one can only get a partial and incomplete picture at any point in time (Liu, 2012). This makes renders most important the general processes depicted by Wilkins.

In assuming executive power, in-house counsel risk professional dominance. As a matter of professional ethics in the United States, lawyers cede most final forms of control to their client, the organization (ABA, Rule 1.2). Decisional authority over the scope and content of legal work, however, may be allocated within an organization by dynamics driven by other than the norms of the legal profession.

Outside the business sector, in-house counsel for organizations – especially public interest organizations – face the possibility and are cognizant of the attendant responsibilities of performing executive tasks for the organizations or causes they take as clients. Cause lawyers fear making decisions that are not properly theirs to make. They also fear not empowering those with whom they work (Sarat and Scheingold, 1998).

In-House Counsel as Professional Actors

Professions whose professionalization projects stress autonomous employment as a hallmark of the profession – the 'liberal' professions – may denigrate employed lawyers for lacking professional independence. Although organizational

employment had not been derogated in the United States, during the progressive era, in-house counsel began to be called 'kept lawyers' (Rosen, 2010a). In the European Union, unlike self-employed lawyers, in-house counsel are not legally privileged to protect the confidentiality of their work product or client communications (Akzo Nobel, ECJ, 2010). In many civil law countries, a lawyer must resign from the bar before taking salaried employment. In liberal professions, a 'heteronomously employed' legally trained individual who performs legal work, such as an in-house counsel, may not be professionally respected as a 'lawyer.'

The substantive claim in the professional denigration of in-house counsel is their supposed lack of professional independence. Organizational control over the work of professionals, from a legal perspective, creates a potential conflict of interest. The in-house counsel may not pursue professionally proper work, instead, they may be led by organizational interests. Nelson and Nielsen (2000) described three ideal types of inside counsel. One, the 'cop,' would police organizational interests, pursuing legal ends. The second, the 'counsel,' would better align legal services with the interest of the organization and, while not negating legal ends, would maximize corporate ability to 'comply' with the law, raising issues of 'creative compliance' (McBarnet, 2004). Nelson and Nielsen's third ideal type was the inside counsel as 'entrepreneur,' who understood the law (and his or her job) to be a means for making money for the corporation. An entrepreneurial inside counsel may misalign the corporation with legal goals.

The claim that inside counsel lack independence suggests that others have greater amounts of independence. The professional independence of in-house counsel is relative to that which can be bought in the market. Sung Hui Kim compared inside and outside counsel by their (1) 'willingness to interdict' illegal activities, (2) 'willingness to monitor' organizational activity, (3) 'capacity to monitor,' and (4) 'capacity to interdict' (Kim, 2008). Kim argued that inside counsel have increased 'willingness' and 'capacity to monitor,' making them superior to outside counsel as protectors of legality in ordinary cases. On the other hand, obedience pressures in extraordinary cases may make inside counsel less able than outside counsel to interdict corporate wrongdoing. In other work, Sung Hui Kim has examined the psychological pressures that may keep inside counsel from pursuing professional ends even when there is not strong corporate resistance to doing so (Kim, 2005, 2011). Especially as compared with outside counsel, others contend that inside counsel are not only able but are also willing to be carriers of legal independence inside the company (Hackett, 2012) (but see Wallace, 1995).

The law jobs performed by in-house counsel may be bought by the corporation by contracting with external providers. In the marketplace, there are sellers of legal services in professional law firms, multidisciplinary practices, legal process outsourcing services, and competing professions. In-house counsel compete with autonomously employed lawyers who compete with accounting–consulting firms, regulatory engineering specialists, and business advisors of many sorts.

In-house counsel, in the United States, have become the purchasing agents for the corporation in regards to legal services (compare Rosen, 1989 with Rosen, 2002b). This hiring control has altered the distribution of deference within the legal profession, with independently employed lawyers no longer denigrating in-house counsel. In fact, "He who pays the piper calls the tune," describes the current professional hierarchy in corporate law, almost as much as it attests to mere business power. As Donald Langevoort puts it, "many outside lawyers are seeking to channel the values, language, habit, and mind-set of in-house counsel elites in order to become synchronous with their preferences." (Langevoort, 2012: p. 497).

As expert purchasers of the work of outside legal service providers, inside counsel increase the organization's ability to monitor the legal services purchased and consequently may decrease external providers' abilities to be independent. Sometimes, in-house counsel may demand that external providers be independent. Other times, in-house counsel's influence on whom and when to hire in the external market can decrease external providers' willingness and capacity to exert their independence. In-house counsel also decrease the abilities of external providers to be independent by inhibiting personal relations between outside providers and organizational members and by limiting the time frame in which the external providers respond or the problems they are posed. By retaining authority to select external providers, to define the goals of their work and to define the problem which is the subject of legal work, organizations control what legal services they purchase in the market, decreasing the professional independence of external providers (Kagan and Rosen, 1985).

The independence of in-house counsel also is relative to the organizational roles they assume. First, in-house counsel may be delegated or may assume organizational decisional authority. In-house counsel vary in the extent to which they are assigned thick responsibility in their organizations. Second, organizations differ not only in their enacted cultures but also in the extent to which they seek to gain the advantages of in-house counsel's commitment to the organization by supporting job enrichment schemes that may mirror the rents of professional privileges. In-house counsel may become trusted organizational actors and may use that trust to exercise what could be seen as professional independence. And third, organizations differ in their internal politics so that in-house counsel may have opportunities to assert their independence by bargaining and other political activities.

Legal professions differ in where and how they establish the lack of plasticity in professional work that is deemed to warrant the assertion of professional independence. During much of this century, there have been calls for in-house counsel to serve as consciences for their organizations. In the U.S. business sector, where in-house counsel have attained organizational power, this call is seldom heard. Nor on the agenda are limits on what information about the law in action in-house counsel may professionally provide. As risk management replaces law compliance as the legal department's governing philosophy, regulatory inaction and inattention – not only legal norms – become part of the calculus of legal advice. Students of professions thus may study inside counsel to gain information about the plasticity of the professional legal role.

In their work, in-house counsel attest to the law's legitimacy for the organizations they serve and apply professional

knowledge. Yet in-house counsel are employees, and therefore are subject to workplace norms and business priorities that may be determined by executives outside their control. Inside counsel and their work create subjects for research for students of both organizations and professions.

This article is a revision of the previous edition article by C.W. Roberts, volume 11, pp. 2697–2702, © 2001, Elsevier Ltd.

Abstract

Unintentional injuries are a major public health problem in developed and rapidly developing countries. The causes of injuries and accidents may be studied from an epidemiological or psychological perspective. Psychological research in this area has identified personality traits, error proneness, demographic factors (such as age), risk-taking behavior, general life stress, and work-related stress as underlying factors in accidents. Injury prevention efforts have focused on safety education, modification to the environment, and behavioral change. Further research is needed to explore the most effective means of intervention to prevent accidents and injuries in future.

Accidental or unintentional injuries are a leading cause of death in developed countries (WHO, 2008; US National Centre for Injury Prevention and Control, 2010). For example, in the United States, unintentional injuries result in more than 180 000 deaths, an estimated 2.5 million people hospitalized, and an estimated 31.6 million people treated in hospital emergency departments every year (US National Centre for Injury Prevention and Control, 2010). In addition to the human costs associated with injuries, there are also substantial economic costs in terms of health care and lost productivity, affecting families, communities, and societies. Accidents and injuries can occur across many types of activity, including accidents at work, road traffic accidents, accidents in the home, and during leisure activities. The leading cause of unintentional injuries varies by age group, with young children most likely to be injured in the home (including unintentional suffocation, drowning, and poisoning), while older children and young adults (5–24 years of age) are most likely to be victims of motor vehicle crashes (WHO, 2008).

Advances in safety equipment, technology, and safe practices have combined to reduce the risk of death from unintentional injuries over recent years. For example, over the previous 30 years, child injury rates have declined by up to 50% in many developed countries; nevertheless, unintentional injuries remain a significant problem, still accounting for 40% of all child deaths in the developed world (WHO, 2008). The scientific study of accidents and injuries can help us to further understand the underlying causes of accidents and how to prevent them, as individuals, organizations, and societies.

Scientific Study of Injuries and Accidents

The study of injuries and accidents is multidisciplinary, drawing on research conducted across a number of different scientific disciplines. Scientific research aims to develop the knowledge of how and why injuries result from unintentional events (or accidents) and how they can be prevented or controlled.

Epidemiological Approach

One approach to the study of injuries is based on epidemiology, which identifies the multiple factors leading to injuries. Injuries occur due to the interaction of a person with an environmental hazard that leads to bodily damage within a short period of time (to distinguish injury from disease, which manifests over a longer time period; Haddon, 1980).

The epidemiological approach is focused largely on description, rather than analysis, of the causes of accidents. For example, a cyclist is injured when knocked from his or her bicycle by a car when cycling on a busy road; the injury can be described in terms of the 'host' (e.g., cyclist), the 'agent' (e.g., other road user), and the 'environment' (e.g., condition of the road, volume of traffic, time of day, etc) based on the work of Haddon (1980). Such an approach provides an insight into patterns and trends of injuries, leading to a better understanding of their occurrence, as well as their severity and impact. For example, an understanding of injury mechanisms, such as head trauma, can help in the design of effective helmets to prevent or reduce the severity of injuries (e.g., helmets worn by cyclists, horse riders, or skiers, where the risk of head injury is high).

Psychological and Sociological Approach

A more analytical approach to the study of accidents and injuries focuses on understanding the underlying causes of accidents that lead to injuries. Research in this area has demonstrated the substantial role played by human factors, such as human error, ergonomics (interaction between people and equipment), personality, and risk-taking behavior, as well as broader factors, such as organizational policies and practices, cultural norms, and social climate.

Accident causation theories emphasize that multiple factors combine to cause accidents, rather than having a single cause. For example, Heinrich's domino theory (1932) links accident causation to a sequence of events in which one event triggers the next (like the falling of dominos). Events in the sequence may relate to characteristics of the environment (e.g., unsafe conditions), as well as characteristics of people (e.g., unsafe behavior). More recently, accident theories have broadened their scope to consider the interaction of factors (e.g., socio-technical system theories) and the wider context of the system (e.g., macroergonomic theories) (Khanzode et al., 2012). These theories emphasize the importance of understanding the interaction between people and the wider context (e.g., organizational, environmental, and societal factors) in the

causation of accidents. For example, an employee may injure himself or herself at work, when using a piece of equipment; accident causation theories focus on understanding the role of human factors (such as carelessness, rule-breaking, and lack of attention), ergonomics (such as the design of the equipment and its fit with the person using it), job-related factors (such as time pressure and workload), and wider organizational factors (such as the quality of supervision and the safety culture).

Research concerned with accident causation is largely the domain of psychologists, sociologists, and behavioral scientists. Understanding people's behavior not only provides an insight into how accidents and injuries occur, but also helps develop effective strategies to ensure that people use safety equipment, such as car seat belts and safety helmets, which have been designed to protect them.

Causes of Injuries and Accidents

Accidents were once viewed as 'acts of God,' which cannot be predicted or controlled. Indeed, if we speak of something happening 'by accident' we usually mean it was unintentional, unavoidable, and happened by chance. Although the negative consequences of accidents are unintended, most accidents do involve an element of chance; however, research has shown that accidents are most frequently caused by a combination of multiple factors, many of which can be predicted and controlled. Not all factors can be controlled, but understanding their influence allows us to develop interventions to mitigate their effects.

Accident Proneness

You might expect that, all things being equal, each one of us has the same likelihood of being involved in an accident. However, research has demonstrated that this is not the case. In fact, accident data consistently reveal that a very few people are involved in a disproportionately high number of accidents (Visser et al., 2007). The discovery of 'accident repeaters' led early researchers to hypothesize that some people are accident-prone, meaning that they suffer injuries more often than would be expected by chance, due to a stable set of personal characteristics. However, despite statistical evidence supporting the idea of accident proneness, researchers have had little success in identifying an underlying set of psychological traits or characteristics that make some people accident-prone and others not (Clarke, 2011).

There is evidence to suggest that accident proneness is stable over time (af Wåhlberg and Dorn, 2009), but an enduring set of psychological characteristics that can account for this stability has not been identified. However, psychological research has identified a number of distinct characteristics that are significantly associated with higher accident involvement, including personality traits, decision-making style, and the tendency to suffer cognitive failures, such as forgetting things.

Personality and Other Individual Differences

Information-processing skills are required to avoid accidents, as people must be able to rapidly recall information, identify problems quickly, and react swiftly to unexpected situations. Indeed, analyses of accident causes have found that ineffective processing of information, lack of attention, and poor judgment are the most common precursors of accidents (Brown, 1990). These reflect the psychological phenomenon known as 'cognitive failure,' which is characterized by forgetfulness and distractibility. It relates to the ability to distribute attention across multiple tasks, particularly under stress; this is a cognitive ability that is relatively stable over time, but is not specifically related to intelligence. People with a higher tendency toward cognitive failures (i.e., those who are error-prone) are more likely to have accidents (Wallace and Vodanovich, 2003). They are also more vulnerable to the symptoms of stress, such as depression, anxiety, difficulty sleeping, and general ill health.

Clarke and Robertson (2005) conducted a comprehensive review of studies linking personality traits to accident involvement; they found that people who are more agreeable (pleasant, tolerant, and diplomatic) and conscientious (dependable, compliant, and self-disciplined) are involved in fewer accidents overall. At the opposite pole of these personality traits were those who were most likely to be involved in accidents. These people tended to be more hostile, belligerent (low in agreeableness), impulsive, and noncompliant (low in conscientiousness). Personality traits predispose people to behave in certain ways, which can increase their chances of being involved in an accident. For example, people who are low in agreeableness tend to respond aggressively to situations, take risks, and break rules, increasing their risk of an accident. Clarke and Robertson's (2005) review also looked at work and traffic accidents separately. They found that people who are extraverted (sociable, outgoing, and sensation-seeking) are involved in more traffic accidents, while those who are neurotic (emotionally unstable, anxious, and worried) have more accidents at work. Extraverts tend to be sensation-seekers who are more likely to take risks, such as driving too fast; they are also more prone to fatigue-related driving errors. Neurotics tend to experience more negative emotions and cope less well with stressful situations, making them more likely to be injured at work.

In summary, psychological research has shown that some personality traits affect people's ability to concentrate, manage stressful situations, succumb to fatigue, take risks, and break rules, and so influence their likelihood of having an accident and being injured.

Demographic Factors

Age is a demographic factor associated with accident liability. Both older (>64 years) and younger (<30 years) age-groups have greater frequency of accidents and injuries compared to middle-aged people. It is a common assumption that younger people are accident-involved because they are immature risk-takers, while older people are more accident-involved because of the decline in their mental faculties. However, research suggests that both views may be stereotypes and not fully supported by research.

As we grow older, our liability to suffer accidents and injuries tends to increase. For example, older drivers experience an increased probability of accidental injury of up to 45%

compared to other drivers. This increased injury liability is not necessarily linked to a loss of driving skills, but may be related to other psychological mechanisms associated with aging, such as changes in circadian and sleep systems. For example, older drivers tend to have more accidents in afternoons due to drowsiness than younger drivers (Smolensky et al., 2011). Moreover, the effect of higher accident liability is reduced if driving distance is taken into account.

Higher accident rates among younger drivers (<30 years) are often viewed as resulting from reckless behavior, which tends to be outgrown as individuals mature. Indeed, research indicates that younger drivers and young men, in particular, commit the highest levels of driving violations. However, overtly risky behavior only accounts for a small proportion of young people's accidents, which occur largely as the result of errors (McKnight and McKnight, 2003). Higher crash rates tend to disappear rapidly with increasing experience, suggesting that the majority of accidents are caused by inexperience rather than dangerously risky behavior.

Recent research looking at the effect of aging in the workplace has suggested that 'work ability' is more important than chronological age, as people tend to age at different rates (Costa and Sartori, 2007). Work ability takes into account situational factors that affect a person's work efficiency (e.g., type of work), as well as his/her actual age. Work ability can be augmented as the result of interventions, which allow the work environment to be adapted to better fit a person's capability.

General Life Stress and Work-Related Stress

The analysis of accident statistics has suggested that people may experience temporary 'spells' when they have increased vulnerability to accidents. These 'spells' would suggest a temporary cause, rather than an enduring predisposition for accident involvement. One possible explanation would relate to the experience of significant periods of stress, which can reduce efficiency and increase accident risk (Clarke, 2011). Major life events, such as divorce or bereavement, cause many people to experience high levels of stress, which increase their vulnerability to accidents and injuries. One research study (Legree et al., 2003) found that life stress in drivers was strongly associated with higher involvement in road accidents. Even minor daily hassles and work-related stress are related to traffic accidents, suggesting a spillover effect of stress experienced outside the driving environment on driving behavior (Rowden et al., 2011). Daily hassles were found to increase the likelihood of both errors (such as cognitive failure) and violations (rule-breaking, such as speeding and tailgating). Stress may affect safe driving behavior by acting as a source of distraction (making errors more likely) and also through emotional 'venting' (such as driving too fast).

Clarke (2012) found that work stress had a significant effect on employees' safe behavior and their accident involvement in the workplace. The most negative effect was associated with 'hindrances'; those situational factors that cannot be controlled, such as daily hassles, conflict with supervisors or coworkers, workplace politics, and concerns about job security. These stressors were found to significantly increase the occurrence of injuries at work, by reducing participation in safety activities (such as reporting faults or attending safety training) and compliance with safety rules (such as following safety procedures or wearing protective clothing). Further research has shown that stress at work can have a spillover effect to other activities, such as driving, leading to more traffic accidents (Rowden et al., 2011).

Risk-Taking Behavior

Risk-taking is usually associated with reckless behavior often in violation of safety rules (such as speeding or drunken driving) but can also relate to high-risk leisure activities such as skiing, skydiving, or mountaineering (which involve known hazards). A review of research looking at the effect of risk-taking on the likelihood of sustaining an injury found that both risky behavior and a sensation-seeking personality led to increased injuries (Turner et al., 2004). The personality trait of sensation-seeking (an aspect of extraversion) predisposes people to seek thrills through taking risks and deliberate rule-breaking (violations). This personality trait has been associated with increased crash risk. Although Turner et al. (2004) supported these findings, they also found that for dangerous sports (such as skiing) the personality trait of sensation-seeking was protective of injury, meaning that sensation-seekers were less likely to be injured. This protective effect was found as those who scored highly on sensation-seeking were also the most skilled skiers.

Risk assessment and evaluation are important psychological processes associated with accidents and injuries. Research conducted on traffic accidents has found that the ability to recognize and assess the risk associated with environmental hazards, such as road conditions, visibility, and weather, is critical to safe driving. These abilities become more sophisticated with driving experience. Risk-taking may occur when hazards have been correctly assessed, but no action is taken to mitigate the risk. For example, the driver correctly identifies that thick fog represents a significant hazard, but fails to reduce speed and increase distance to the next vehicle accordingly. In addition to cognitive processes, risk-taking involves emotional processes as well. For example, Legree et al. (2003) found that drivers who were less competent at managing their own emotions were more likely to be involved in traffic accidents during periods of stress (caused by major life events, such as divorce). Drivers with better emotional awareness were able to adjust their driving behavior to reduce crash risk when they felt emotional and under stress.

Overall, risk-taking behavior increases accident and injury risk by increasing cognitive failure and violations. However, risk-taking involves not only cognitive processes, but also emotional processes, such as thrill-seeking, and emotion awareness and management.

Accident and Injury Prevention

There are a number of different approaches to the prevention of unintentional injuries. These range from education (providing information and training) to product or environmental modifications, behavior modification, and enforcement (regulations and legislation). While changes to regulation and legislation can be effective in changing behavior, public education campaigns

are often needed to encourage behavioral change (e.g., UK legislation to enforce the wearing of car seat belts introduced in 1983 was preceded by the 'clunk click' media campaign during the 1970s). Other approaches focus on interventions designed to reduce or eliminate hazards (environmental modification) or change people's behavior (behavior modification).

Health and Safety Education

Health and safety education is a frequently used method for targeting injury prevention; it focuses on educating people about the hazards in a particular environment (e.g., educating pedestrians about road safety) and providing them with strategies to better cope with those hazards (e.g., learning how best to check for oncoming traffic before crossing the road). A review of the effectiveness of education-based interventions to reduce pedestrian injuries in children (Duperrex et al., 2002) found significant effects on changing road safety behavior. However, a lack of data meant they were not able to establish if these behavioral changes led to reduced injuries. Further research has examined educational interventions aimed at the road-crossing behavior of elderly pedestrians (Dommes and Cavallo, 2012). Although there were short-term effects, in the longer term elderly pedestrians still made poor judgments regarding the speed of approaching vehicles, which affected their decision to cross. Where it is not possible to change such behavior, environmental modifications (such as the provision of pedestrian-operated crossings) may be more appropriate.

Environmental Modifications to Achieve Safety

Environmental modification focuses on the elimination or reduction of hazards in order to prevent injuries. This approach is used most frequently in interventions designed to improve safety in the home. It is often targeted at young children (<5 years) and the elderly (>75 years) who are most at risk of injury in the home environment (e.g., falls, burns/scalds, and poisoning). Most interventions are multifactorial, recognizing the role of multiple factors in accidents, and so often involve an element of education and advice, as well as changes to the domestic environment (e.g., installation of stair gates, locks on cupboards, better lighting in hallways and on stairs, etc.).

A recent review examined the effectiveness of home safety interventions (which provided one-to-one face-to-face education in the home and free/discounted safety equipment) and found they were successful in changing safety practices of mothers with young children (Kendrick et al., 2013). Although safety practices may be improved using interventions, the evidence concerning injuries remains inconsistent (Kendrick et al., 2013; Turner et al., 2011). Turner et al. (2011) were not able to find evidence that home safety interventions are effective in reducing injuries in children and the elderly. However, this was due to the lack of systematic evaluation studies, rather than an indication that these interventions do not work.

Behavioral Modification

Behavior modification focuses on specific unsafe behaviors, such as not wearing safety equipment at work, or failing to put on a car seat belt. The objective of behavior modification is to change the way that people behave, rather than to change environmental hazards. It is often used as a way of further reducing the risk of injury, where hazards have already been reduced to the lowest possible level, or ensuring people use safety equipment designed to protect them from injury (e.g., in the workplace). Behavior modification works by changing either (1) the triggers or prompts, or (2) the consequences of behavior. For example, employees may not wear safety gloves because they are uncomfortable and reduce their productivity; by introducing a financial reward for wearing safety gloves, behavior will be changed. Once a new behavior is learned and becomes habitual, the intervention can be withdrawn, but the new behavior will continue (e.g., even though they no longer receive a financial reward, employees continue wearing safety gloves as they put them on as a habit when starting work, they have got used to working with them on and everybody else is wearing them). The behavioral change approach is not suitable in all circumstances, as it tends to work best for very specific behaviors that are easily observed and monitored.

Behavioral science models are extremely useful for guidance in the design of interventions. There is evidence that interventions based on behavioral theory are much more successful in changing behavior, than those that are not. Behavioral modifications are often very effective in changing behavior in the short term, but behavior can drift back unless attitudes to safety and behavioral norms change in the longer term. The most successful changes are achieved when there is not only behavioral change, but also a change in work climate and workers' safety attitudes (Cooper et al., 1994). This means that one person's new behavior is supported by everyone around him or her (e.g., it is easier to keep wearing safety gloves when all your workmates wear them too and believe that they are essential for safety).

Future of Injury and Accident Research and Prevention

The overview of different approaches to injury prevention has shown that each type of intervention can be effective in some circumstances, but there is not one best way to prevent accidents and injuries. In terms of the future, there needs to be more research focused on identifying the right place for the right intervention. There also needs to be more rigorous evaluation of the effectiveness of interventions and further large-scale studies where data are currently lacking; for example, home safety interventions (Turner et al., 2011; Kendrick et al., 2013), safety education (Duperrex et al., 2002), and the use of combined approaches (Dommes and Cavallo, 2012).

Another area for further investigation is the use of technology to improve safety. For example, as many accidents are due to distraction and cognitive failure, automated systems have been designed to reduce the risk of accidents. In-car technologies, such as adaptive cruise control (ACC), are increasingly being introduced into vehicles to reduce driving errors. A research study (Ward, 2000) found that the use of ACC led to improved driving performance by reducing errors, such as following too close. However, it also had the effect of reducing situation awareness (e.g., lane positioning, yielding to

other traffic, slower response times to unexpected events). This research demonstrates that in-car technologies can have unintended consequences, such as diverting attention to the automated system away from controlling the vehicle and monitoring for external hazards. If automated systems are to be successful in reducing accidents, they must be designed around the person, taking psychological effects into account.

Injustice: Legal Aspects

Abstract

This article explores the meaning of injustice by contrasting it with misfortune. It then explores varying ways in which people respond to injustice. It argues that the fact that most people respond to injustices by doing nothing provides an important factor to be considered in the discussion of the so-called 'litigation explosion.' Yet commentators from Plato to Derrida have called law to account in the name of justice, scolding and chiding it for the injustices which it does, promotes, or tolerates. They also recognize that all too often law, in this culture and elsewhere, is a tool of injustice. For every step taken toward realizing the good, an equal, if not greater, number have been taken in the name of evil. These commentators have asked that law provide a language for responding to injustice and demanded that it promotes, insofar as possible, the attainment of a just society. This article examines various responses to this demand and points to the need for contextual and particularlistic examination of both individual responses to injustice and of law's proper role in the promotion of a just society.

What is injustice? Is it simply the absence of justice, the opposite of a utopian achievement? Or does it have a life of its own? Is it possible to disentangle the experience of injustice from the dissatisfactions and disappointments that people experience everyday? How should an understanding of injustice affect our thinking about law? These are the questions to which any student of injustice must ultimately address himself or herself.

The best recent treatment of the subject of injustice and its complex relations to justice and law is found in Judith Shklar's *The Faces of Injustice* (1990). Shklar (1990, p. 19) tries to rehabilitate injustice as a subject of study, arguing that it "should not be treated intellectually as a hasty preliminary to the analysis of justice." According to Shklar (1990, p. 19; also Cahn, 1949; Folger, 1984), "The real realm of injustice is not in an amoral and prelegal state of nature. It does not appear only on those rare occasions when a political order wholly collapses. It does not stand outside the gate of even the best known states. Most injustices occur continuously within the framework of an established polity with an operative system of law, in normal times."

Shklar recognizes that injustice exists at one end of a continuum of human experience and is often confused with other undesirable conditions. To avoid such confusion, the study of injustice must be differentiated from what she calls misfortune. "When is a disaster a misfortune and when is it an injustice?," Shklar asks. For her the answer is to be found in the presence or absence of a responsible human agent. "If the dreadful event is caused by the external forces of nature, it is a misfortune and we must resign ourselves to our suffering. Should, however, some ill-intentioned agent, human or supernatural, have brought it about, then it is an injustice and we may express indignation and outrage" (Shklar, 1990, p. 1).

This analysis treats injustice as a matter of malevolent human action, rather than as a matter of structure or of institutional design. It embodies what Gordon (1996, p. 36) calls the perspective of 'narrow agency,' in which injustice is thought of as a wrong 'done by specific perpetrators to specific victims.' But Gordon suggests that the danger of this perspective is that it will lead us to ignore other kinds of injustices. He reminds us that injustices can be done by collective perpetrators to collective victims, such as the Nazi atrocities against the Jews. This kind of injustice involves what he calls 'broad agency.' In addition, injustice can be attributed to bad structures in addition to bad agents. An interest in this kind of injustice 'takes the form of explanations rather than a search for villains and attribution of blame.'

Responses to Injustice

Whether defined in terms of narrow agency, broad agency, or structure, some believe that in the United States people are too ready and eager to use the language of injustice and to turn to law to redress conditions which in the past would have been regarded as the uncontrollable workings of fate. Typical is Lieberman's (1981, p. xi) contention that ours "is a law-drenched age… Though litigation has not routed out all other forms of fight, it is gaining public favor as the legitimate and most effective means of seeking and winning one's just deserts. So widespread is the impulse to sue that litigation has become the nation's secular religion." In this view, our legal culture is today governed by two principles (Friedman, 1985, p. 43). "The first… is the citizen's expectation of fair treatment, everywhere and in every circumstance … The second… is the general expectation that somebody will pay for any and all calamities that happen to a person …." Together these two principles create a culture of 'total justice' (Friedman, 1985) and what some believe to be a 'litigious society' (Lieberman, 1981; Huber, 1988).

In an article I co-authored in 1980, my co-authors and I argued that responses to injurious events are more complicated than arguments about 'total justice' or the 'litigious society' admit. These responses, we noted, could be understood as occurring in three stages (Felstiner et al., 1980–81). The first, defining a particular experience as injurious, we called 'naming.' The next step in the emergence of a claim of injustice is the transformation of a perceived injurious experience into a grievance. This occurs when a person attributes an

injury to the fault of another individual or social entity' (Felstiner et al., 1980–81, p. 635). It involves 'blaming.' The third step occurs "when someone with a grievance voices it to the person or entity believed to be responsible and asks for some remedy" (Felstiner et al., 1980–81, p. 635). This step we called 'claiming.'

It was our contention that "only a small fraction of injurious experiences ever mature into disputes. Furthermore, we know that most of the attrition occurs in the early stages: experiences are not perceived as injurious; perceptions do not ripen into grievances; grievances are voiced to intimates but not to the person deemed responsible" (Felstiner et al., 1980–81, p. 636). Paying attention to the process through which responses to injustice are formulated and to the high rate of attrition in, or resistance to, the making of claims was, we contended, a way of putting the burgeoning argument about the litigation explosion in context. We argued that the processes through which claims emerge, or through which people decide to 'lump it,' are "subjective, unstable, reactive, complicated, and incomplete" (Felstiner et al., 1980–81, p. 637). Most of what occurs in this domain is cultural, not legal, occurring as it does in the everyday lives of ordinary citizens and in their struggles to make sense of who they are and who they want to be in a world of risk, danger, and injury (Sarat, 2000) (*see* Legal Culture and Legal Consciousness).

Since then, some scholars have studied the way in which people actually react to the injurious events of their lives (Merry, 1990; Yngvesson, 1993; Greenhouse, 1986; Ewick and Silbey, 1998). That scholarship characterizes litigation as a process of contesting meanings and adjudication as the choice and imposition of one structure of meaning over another (Merry, 1990). Contests over meaning in courts or communities thus become occasions for observing the play of power. Meanings which seem natural, or taken for granted, are described as hegemonic, but because the construction of the meaning of injurious events is, in fact, typically contested, scholars show the many ways in which different people respond to injustice. They have found that the tendency to label injurious events in the language of injustice is contingent and complex, varying from one community to the next, from one kind of injury to another.

In this process, law plays a key role. As Merry sees it, the relationship between injustice and law is not one in which law passively responds to expectations for 'total justice.' Law works, she says (Merry, 1990, pp. 8–9), "not just by the imposition of rules and punishments but also by the capacity to construct authoritative images of social relationships and actions, images that are symbolically powerful. Law provides a set of categories and frameworks through which the world is interpreted. Legal words and practices are cultural constructs which carry powerful meanings not just to those trained in law … but to the ordinary person as well." Merry's research shows that responses to injustice involve "a complex repertoire of meanings and categories understood differently by people depending on their experience with and knowledge of the law" (Merry, 1990, p. 5). This work connects the study of injustice to the world of law and is continuous with a long history of scholarship about the connections between law and justice and about the ways law is implicated in injustice.

Injustice and Law

Commentators from Plato to Derrida have called law to account in the name of justice, scolding and chiding it for the injustices which it does, promotes, or tolerates. They also recognize that all too often law, in this culture and elsewhere, is a tool of injustice (see, for example, Cover, 1975; Irons, 1983). For every step taken toward realizing the good, an equal, if not greater, number have been taken in the name of evil. These commentators have asked that law provide a language for responding to injustice and demanded that it promote, insofar as possible, the attainment of a just society.

They have done so, however, in relentlessly abstract and general language, as if the demands of justice and the problem of injustice could only be apprehended accurately outside of history and context, and as if only philosophers were fit to engage in conversation about these subjects. The justice which is spoken about is, as a result, elusive, if not illusory, and disconnected from the embodied practices of law of the kind that Merry emphasizes. As one writer noted, "there is no such thing as justice 'in general,' one can meaningfully discuss only fairly concrete injustices and procedures for their mitigation with existing social machinery or possible ways of improving the overall social organization" (Knight, 1963, p. 1).

The turn to injustice is generally associated with an interest in context and particularity, in which attention is given to individuals and institutions and their contingent histories. In one sense, then, when scholars talk about injustice and try to connect it to law they are often reacting against the vexing difficulty that attends to the effort to examine the connection of law and justice.

In earlier days, however, speaking about law and justice was not so vexing or difficult. Justice (*jus*, meaning 'law') was a legal term, pure and simple. At the outset, then, justice was defined and constituted by laws that were 'given' and held to be unchanging and unchangeable. This ineluctable link between justice and law had the virtue of making the boundaries of justice more or less clear, but it had the considerable vice of labeling even heinous, iniquitous laws just. Attention to the problem of injustice could do no critical/reconstructive work in legal scholarship because it was impossible to think of justice as external to law.

Hobbes (1958) to the contrary notwithstanding, most natural law thinkers have resisted this result by insisting that unjust laws are not law (see, for example, Aquinas, 1988; George, 1992; Finnis, 1890; Hittinger, 1987). Doing so meant the end of any easy identification of positive or human law with 'real' or binding law. The alternative, embraced by perhaps a majority of those who do legal philosophy (Hart, 1961; for an important contrast, see Fuller, 1964), is to cut justice and law free from one another, to insist that justice is more than mere conformity to law and to acknowledge that even unjust laws might nonetheless be law. This has freed students of injustice to direct their attention to the practices of law itself, scrutinizing them for their contributions to injustice in society.

More recently, the distance between law and justice, and the potential for injustice in the name of the law, have been recognized in postmodern theorizing about ethics (Cornell, 1988, 1992). Thus, as Douzinas and Warrington (1994, p. 23)

(see also Keenan, 1990) argue: "Justice has the characteristic of a promissory statement. A promise states now something to be performed in the future. Being just always lies in the future, it is a promise made to the future, a pledge to look into the event and the uniqueness of each situation …. This promise, like all promises, does not have a present time, a time when you can say 'there it is, justice is this or that.' Suspended between the law and the good …, justice is always still to come or always already performed."

Severance of the definitional tie between justice and law has left both notions free (if also bound) to acquire new identities (Balkin, 1994). It has opened the way for an examination of unjust actions or conditions and for an inquiry into the ways law is implicated in them. However, this definitional separation has by no means put an end to the commonplace conviction that the principal home of justice is law and the special concern of law, perhaps its principal business, is justice. As Clarence Morris (1963, p. 170) notes, "Though there can be law without justice, justice is realized only through good law." In fact, law and legal theory continue to be shaped by concerns about justice and injustice, just as understandings of these notions are shaped by an awareness of law and the concerns of legal theory (Lucas, 1980).

From Law to Politics in the Study of Injustice

By what might fairly be regarded as an accident of intellectual history, concerns about injustice as a motive for studying and reforming law have been somewhat muted in some contemporary discourse which seeks to expand interest in injustice beyond the sphere of law. They have been swamped by a preoccupation with distributive justice, a subject whose contemporary pre-eminence can unquestionably be attributed to John Rawls' *A Theory of Justice* (1971). 'Justice,' Rawls (1971, p. 3) contends, "is the first virtue of social institutions, as truth is of systems of thought." But the justice he has in mind is almost exclusively distributive justice, not justice more broadly construed; injustice of a distributive type is not peculiarly the concern of law at all.

Similarly, the philosopher Agnes Heller (1987, p. 54) introduces the notion of a broad, though incomplete, "ethico-political concept of justice." In her view, justice and injustice are not simply about principles of distribution; they concern the perspectives, principles and procedures for evaluating institutional norms and rules. Developing themes in Habermas's (1987) communicative ethics, Heller (1987, p. 54) proposes that justice is "primarily the virtue of citizenship, of persons deliberating about problems and issues that confront them collectively in their institutions and actions, under conditions without domination or oppression, with reciprocity and mutual tolerance of difference" (Young, 1990, p. 33). Domination, oppression, and intolerance are thus preconditions for injustice.

Iris Young (1990, pp. 34, 37) expands on even this notion, concluding that "the concept of justice coincides with the concept of the political," and while it is "not identical with the concrete realization of these values in individual lives," it is attentive principally to "the degree to which a society contains and supports institutional conditions necessary for the realization" of the values of equal worth as these are promoted or confined in a society's basic institutional arrangements. The study of injustice then moves from law to politics. On this account the subject is as inclusive as the political order itself.

On the Continuing Significance of Procedure

Despite these broad and encompassing views of justice and injustice, the fact remains that injustice is generally thought to be involved in matters of procedure, punishment, and recompense (Aristotle, 1985; Lucas, 1980). Thus, while law in its legislative moments might share with other social institutions certain distributional objectives, it is generally thought that law has a separate and distinctive commitment to doing justice, located most conspicuously, though not exclusively, in matters of form and process. This is, of course, symbolized in the universal icon of justice (and invariably associated with law): the statue of Justicia, the blindfolded bearer of sword and balance (*see* Rule of Law (and Rechtsstaat); Due Process in Law).

Despite certain ambiguities, Justicia presumably embodies law's central link to justice, impartiality (Curtis and Resnik, 1987). The instrument of Justicia is a balance, not a scale, so it is only a comparative rather than an absolute measurement that is involved. She is blindfolded to prevent her decision from being inappropriately influenced or determined by forces of fear, bias, or favoritism. Moreover, she is blindfolded – not blind – suggesting a self-willed refusal of vision. If we are to avoid injustice, partial justice, or biased justice, what is required is a denial of sight though not of seeing, a regulation of information though not of knowing, a restriction on what is permissibly attended to though not a deficit of attention (Black, 1989).

According to Curtis and Resnik (1987, p. 1727), "procedure is the blindfold of Justice." The proposition that procedure is itself an aspect of justice, and that procedural irregularities are in themselves instances of injustice, takes us some distance toward the further result that law and justice are ineluctably linked. Thus, to the extent that one supposes that the Rule of Law and the principle of legality are constituted largely by a commitment to regularized, self-limiting procedures, it is but a short step to the conclusion that procedural justice is inextricably tied to law itself.

Along some such path, it seems possible to argue further that procedures themselves must meet additional normative requirements, sounding in fairness and desert, and other dimensions of justice. As Hart (1961, Chap. VIII) has observed, a rule that is regularly, uniformly applied to prohibit certain minorities from using the town park might, despite its unfailing enforcement, be viciously unjust. Legal justice, then, involves more than general observance of the rules that regulate exercises of legal authority, the rules themselves must be fair, eschewing wholly arbitrary distinctions between and among the persons to whom they apply or on whom they finally have effect. The rules must provide suitable forms of what, in the United States, are known as requirements of due process and equal protection.

Acknowledging the relationship of procedure and justice has spawned a large and important empirical literature which

explores what leads people to believe that law is just or unjust (Lind and Tyler, 1988; Tyler, 1989). This literature suggests that procedure is more important than substance, that the way one is treated is more important than the results one gets in determining whether people believe that they have been treated justly or unjustly in the legal system. As Lind (1998, p. 184) explains. "If authorities seem to be making decisions in fair ways, people assume that they can obey orders and follow rules without worrying too much about exploitation. If, on the other hand, authorities seem to be reacting unfairly, exploitation becomes a real possibility and obedience tends to be viewed with more suspicion …. Outcome-oriented theories of justice judgements err because they fail to recognize that people are generally quite ready to accept outcomes that are less than they had hoped for."

Can Law Overcome Injustice?

Returning to the questions with which we started, we have seen that injustice is not simply an absence of justice, that it is a fact and an experience different from, though related to, misfortune, and that it may involve the relations of one person to another, of groups of people, and of the attributes of legal, political, or social structure. Though some would focus the attention of persons interested in understanding injustice fairly broadly, law seems to be at the center of any proper understanding of injustice.

Yet having envisaged ways of connecting the study of injustice and of law, it must be granted that not everyone regards the imagined association as an unalloyed good. Hayek (1982), among others, is persuaded that social justice is a mirage, a misguided affection the pursuit of which not only threatens liberty but, eventually, law itself. A somewhat more moderate concern is that the demands of distributive justice and the Rule of Law are inevitably at odds with one another, so that the effort to cure distributive injustices comes at a high price to law itself (Unger, 1977; Barnett, 1988). A third apprehension is that the meaning of justice is so ambiguous, expansive, and elusive that law invariably will be seen as falling short, as failing to meet justice's demands, as always, then, implicated in injustice. As Balkin (1994, p. 16) argues, laws apportion responsibility, create rights and duties, and provide rules for conduct and social ordering. Law is always, to some extent and to some degree, unjust. At the same time, our notion of justice can only be articulated and enforced through human laws and conventions. We may have a notion of justice that always escapes láw and convention, but the only tools we have to express and enforce our idea are human laws and human conventions. Our conception of the just relies for its articulation and enforcement on the imperfect laws, conventions, and cultural norms from which it must always be distinguished.

Some worry that law's legitimate authority, such as it is, will be dangerously (and unjustly) eroded (Tyler, 1990). Alternatively, but with consequences no less grave, the impossibility of satisfying justice's demands may eventually be seen as the fault of justice, not of law.

Still other qualms dampen enthusiasm about the possibility of connecting law to the study of justice and injustice. Some believe that the embrace of legal justice is, at best, a rhetorically appealing device for quieting alarm about the excesses and inequities social and economic arrangements inevitably arouse (Hay, 1975). So conceived, legal justice is largely a symbolic response to the incorrigible defects and injustices of liberal capitalist societies, not a positive virtue which these arrangements can promote or make possible (Marx, 1978).

The fear that legal justice can be put to work in the name of legitimating social injustice, for example by 'justifying' outcomes that seem patently, outrageously disproportionate has been expressed in a different voice, and on different grounds, by Shklar (1990). She argues that the focus on justice inhibits the development of a community that both recognizes the culturally constructed quality of boundaries between the ideas of 'injustice' and 'misfortune,' and objects to passive injustice as vehemently as it abhors the active violation of rights. But Shklar's dissatisfaction with a narrow interest in legal justice is pressed even further in her contention that contemporary theory tends almost exclusively to regard injustice as "simply the absence of justice" (Shklar, 1990, p. 15; Woozley, 1973).

On this view, "once we know what is just, we know all we need to know," Shklar (1990, p. 15) writes. Or, as Knight (1963, p. 15) observes, "One misses a great deal by looking only at justice. The sense of injustice, the difficulties of identifying victims of injustice, and the many ways in which we learn to live with each other's injustices tend to be ignored, as is the relation of private injustice to the public order." Scholars such as Shklar and Knight contend that we not only lack a full and coherent account of justice; even if we had one, it would not yield an equally full account of injustice, nor would it confront adequately our calloused complacency regarding vast, yet eliminable, misfortunes.

These observations call to mind a variety of uncertainties and ambivalences regarding the relationship of law and justice, but they fall far short of embracing the extreme position that justice be jettisoned from legal discourse. Rather, they remind us of the vastness of the subject of injustice, of the difficulty of constructing a single account capable of holding together its many strands, and of the space that exists to theorize anew about justice and injustice in law and legal theory.

Inner City

Abstract

A long history of racial segregation, government policy, demographic trends, and industrial shifts in the labor market has contributed to the growth of disadvantaged and under-resourced inner-city neighborhoods especially in older northern industrial cities. The subsequent social and physical isolation of poor families in joblessness inner-city ghettos has disconnected the poor from job opportunities and the socialization processes associated with regular employment. Economic expansion in the 1990s helped to expand the black middle class but the Great Recession reversed much of these gains. Policies that improve the quality of urban public schools and help grow a workforce that is prepared for a modern economy are discussed.

The Rise of the Modern Inner-City Ghetto

One of the legacies of historic racial and class subjugation in the United States is the growing concentration of poor and minority residents in the nation's impoverished inner-city areas. The demand for low-skill blue-collar workers in the North during the early twentieth century, coupled with the rise in southern blacks' economic insecurity brought about by the declining demand for farm labor due to the increasing mechanization of agriculture, helped fuel the migration of blacks to northern industrial cities. In the North, blacks found themselves increasingly segregated in ghettos that previously housed white ethnic immigrants, who themselves were gradually assimilating into American society.

Since 1934, with the establishment of the Federal Housing Administration (FHA), a program necessitated by the massive mortgage foreclosures during the Great Depression, the US government has sought to enable citizens to become homeowners by underwriting mortgages. In the years following World War II, however, the federal government contributed to the early decay of inner-city neighborhoods by withholding mortgage capital and making it difficult for these areas to retain or attract families who were able to purchase their own homes. But the FHA selectively administered the mortgage program by formalizing a process that excluded certain urban neighborhoods using empirical data that suggested a probable loss of investment in these areas. 'Redlining,' as it came to be known, was assessed largely on racial composition.

Although many neighborhoods with a considerable number of European immigrants were redlined, virtually all black neighborhoods were. Home buyers hoping to purchase a home in a redlined neighborhood were universally denied mortgages, regardless of their financial qualifications. This severely restricted opportunities for building or even maintaining quality housing in the inner city, which in many ways set the stage for the urban blight that many Americans associate with black neighborhoods. This action was clearly motivated by racial bias, and it was not until the 1960s that the FHA discontinued mortgage restrictions based on the racial composition of the neighborhood (Bartelt, 1993; Katz, 1993; Kelley, 1993; Sugrue, 1993).

Federal public housing policy contributed to the gradual growth of segregated inner-city ghettos. The federal public housing program's policies evolved in two stages that represented two distinct styles. The Wagner Housing Act of 1937 initiated the first stage. Concerned that the construction of public housing might depress private rent levels, groups such as the US Building and Loan League and the National Association of Real Estate Boards successfully lobbied Congress to require, by law, that for each new unit of public housing erected, one 'unsafe or unsanitary' unit of public housing must be destroyed.

The early years of the public housing program produced positive results. Initially, the program mainly served intact families temporarily displaced by the Depression or in need of housing after the end of World War II. For many of these families, public housing was the first step on the road toward economic recovery. Their stays in the projects were relatively brief because they were able to accumulate sufficient economic resources to move on to private housing.

The passage of the Housing Act of 1949 marked the beginning of the second policy stage. It instituted and funded the urban renewal program, designed to eradicate urban slums, and therefore was seemingly nonracial. However, the public housing that it created "was now meant to collect the ghetto residents left homeless by the urban renewal bulldozers" (Condon, 1991). A new, lower income ceiling for public housing residency was established by the federal Public Housing Authority, and families with incomes above that ceiling were evicted, thereby restricting access to public housing to only the most economically disadvantaged segments of the population.

This change in federal housing policy coincided with the Second Great Migration of African Americans from the rural South to the cities of the Northeast and Midwest, which lasted 30 years – from 1940 to 1970. This mass movement of African Americans was even larger and more sustained than the First Great Migration, which began at the turn of the twentieth century and ended during the Great Depression, and had a more profound impact on the transformation of the inner city. As the black urban population in the North grew, pressure mounted in white communities to keep blacks out. Suburban

 http://dx.doi.org/10.1016/B978-0-08-097086-8.32178-X

communities, with their restrictive covenants and special zoning laws, refused to permit the construction of public housing, and the federal government acquiesced to opposition to the construction of public housing in the neighborhoods of organized white groups in the city. Thus, units were overwhelmingly concentrated in the overcrowded and deteriorating inner-city ghettos – the poorest and least powerful sections of cities and metropolitan areas. In short, public housing became a federally funded institution that isolated families by race and class, resulting in high concentrations of poor black families in inner-city ghettos (Sampson and Wilson, 1995).

In spite of the tremendous obstacles faced by African Americans, inner-city ghetto neighborhoods in the early twentieth century developed a diversified social and institutional structure, characterized by a mix of poor, working, and middle-class blacks and viable institutions (e.g., businesses, schools, churches, and cultural organizations) that fostered a vibrant social and cultural life. This social organization of earlier ghettos helped to buffer the deleterious effects of marginalization and concentrated poverty (Du Bois, 1899; Drake and Cayton, 1962). Despite their disadvantaged status, well into the 1960s most ghetto-dwellers resided in neighborhoods where a majority of adults were employed.

However, in the last quarter of the twentieth century, one of the most significant changes in these neighborhoods was the out-migration of middle-income blacks (Wilson, 1987). Before the 1970s, African American families faced extremely strong barriers when they considered moving into white neighborhoods. Not only did many experience overt discrimination in the housing market, some were violently attacked. Although even fair housing audits continue to reveal the existence of discrimination in the housing market (Massey and Denton, 1993), fair housing legislation has reduced the strength of these barriers. At the same time, middle-income African Americans have increased their efforts to move from concentrated black poverty areas to more desirable neighborhoods throughout the metropolitan area, including white neighborhoods (Quillian, 1999).

This pattern represents an important change in the formation of neighborhoods. In the earlier years, communities undergoing racial change from white to black tended to experience an increase in population density, as a result of the black migration from the South. Because of the housing demand, particularly in the late stages of the succession from white to black, homes and apartments in these neighborhoods were often subdivided into smaller units (Quillian, 1999). However, 1970 marked the end of the great migration wave of blacks from the South to northern urban areas, and two developments affected the course of population movement to the inner cities after that time. Improvements in transportation made it easier for workers to live outside the central city, and industries gradually shifted to the suburbs due to the increased residential suburbanization of the labor force and the lower cost of production. Because of the suburbanization of employment and improvements in transportation, inner-city manufacturing jobs were no longer a strong factor pulling migrants to central cities (Quillian, 1999). Moreover, the increasing suburbanization of employment generated a growing mismatch between the suburban location of employment and the inner-city residence of minority populations (Wilson, 1987). Inner-city joblessness increased as residents had to contend with both fewer employment opportunities nearby and longer commutes to jobs outside the central city (Wilson, 1996).

So with the decline of industrial employment in the inner city, the influx of southern black migration to northern cities ceased and many poor black neighborhoods, especially those in the Midwest and Northeast, changed from densely packed areas of recently arrived migrants to communities gradually abandoned by the working and middle classes (Wilson, 1987, 1996; Quillian, 1999). With the departure of higher income families, the least upwardly mobile in society – mainly low-income people of color – were left behind in neighborhoods with high concentrations of poverty and deteriorating physical conditions. These neighborhoods offer few jobs and typically lack basic services and amenities, such as banks, grocery stores and other retail establishments, parks, and quality transit (Wilson, 1987, 1996; Fox and Treuhaft, 2006). Typically, these communities also suffer from substandard schools, many with run-down physical plants. Two of the most visible indicators of neighborhood decline are abandoned buildings and vacant lots. According to one recent report, there are 60 000 abandoned and vacant properties in Philadelphia, 40 000 in Detroit, and 26 000 in Baltimore (Fox and Treuhaft, 2006).

Segregation in these depopulated inner-city ghettos also aggravated employment problems by weakening informal employment networks and contributing to the social isolation of families and individuals, thereby reducing their chances of acquiring the human capital skills, including adequate educational training, that facilitate social mobility (Massey and Denton, 1993).

The Changing Labor Market for Unskilled Workers

With the decline in manufacturing employment in many of the nation's central cities, most of the jobs for lower skilled workers are now in retail and service industries (e.g., store cashiers, customer service representatives, fast food servers, and custodial work). Whereas jobs in manufacturing industries typically were unionized, relatively stable, and carried higher wages, those for workers with low to modest levels of education in the retail and service industries tend to provide lower wages, be unstable, and lack the benefits and worker protections – such as workers' health insurance, medical leave, retirement benefits, and paid vacations – typically offered through unionization. This means that workers relegated to low-wage service and retail firms are more likely to experience hardships as they struggle to make ends meet. In addition, the local economy suffers when residents have fewer dollars to spend in their neighborhoods (Wilson, 1996; Fox and Treuhaft, 2006).

Two-thirds of job growth has occurred outside the central city as a result of the suburbanization of employment: manufacturing is now over 70% suburban, and wholesale and retail trade is just under 70% (U.S. Department of Housing and Urban Development, 1999). The suburbs of many central cities, developed originally as bedroom localities for commuters to the central business and manufacturing districts, have become employment centers in themselves. For

example, in Detroit, Philadelphia, and Baltimore, less than 20% of the jobs are now located within three miles of the city center (Fox and Treuhaft, 2006).

Accompanying the rise of suburban and exurban economies has been a change in commuting patterns. Increasingly, workers completely bypass the central city by commuting from one suburb to another. "In the Cleveland region, for example, less than one-third of workers commute to a job in the central city and over half (55 percent) begin and end in the suburbs" (Fox and Treuhaft, 2006: p. 32). Sprawl and economic stagnation reduce inner-city residents' access to meaningful economic opportunities and thereby fuel the economic decline of their neighborhoods. For example, in Cleveland, although entry-level workers are concentrated in inner-city neighborhoods, 80% of the entry-level jobs are located in the suburbs and there is little public transportation between these neighborhoods and jobs (Fox and Treuhaft, 2006).

In addition to the challenges in learning about and reaching jobs, there is persistent racial discrimination in hiring practices, especially for younger and less-experienced minority workers. This racial factor affects black males especially seriously. Today, most of the new jobs for workers with limited education and experience are in the service sector, which includes jobs that tend to be held by women, such as waitstaff, sales clerks, and nurse's aides. Indeed, "employment rates of young black women now exceed those of young black men, even though many of these women must also care for children" (Holzer et al., 2003: p. 15). The shift to service jobs has resulted in a greater demand for workers who can effectively serve and relate to the consumer. Many employers, in an extensive study in Chicago conducted by my colleagues and me, felt that, unlike women and immigrants (who have recently expanded the labor pool for service-sector jobs), inner-city black males lack these qualities. Instead, low-skilled black males are perceived as dangerous or threatening (Wilson, 1996).

In the past, all black men had to demonstrate was a strong back and muscles for heavy lifting and physical labor in a factory, at a construction site, or on an assembly line. They did not have to interact with customers. Today, they have to search for work in the service sector, and employers are less likely to hire them because they have to come into contact with the public. Consequently, inner-city black male job seekers face rising rates of rejection (Wilson, 1996).

Concentrated Poverty, Social Organization, and Culture in the Inner-City Neighborhoods

In contrast to socially organized neighborhoods, many segregated inner-city neighborhoods today have few institutional resources and weak and less cohesive social networks. As a result, residents are less able to enforce norms and control undesirable behavior in the community or to act collectively to preserve the quality of neighborhood life. When the effectiveness of formal and informal social control mechanisms drops below a certain threshold, sanctions against nonnormative behavior become ineffective and opportunities for illegitimate activities proliferate in the community (Sampson and Wilson, 1995).

One of the negative implications of living in such highly segregated neighborhoods, which are characterized by widespread joblessness, high rates of crime, and social dislocation, is the exposure to cultural traits that emerge under conditions of chronic racial and economic subordination, which may undermine efforts toward economic and social mobility. In this context, cultural traits refer to the shared outlooks, modes of behavior, values and norms, attitudes, meaning- and decision making, and behavior that are perpetuated and reinforced in highly restrictive social settings. As such, personal agency in these environments is severely limited by the reinforcement of certain behaviors and habits that are acquired over time under conditions of chronic disadvantage. In addition, the stock of social and human capital that one is likely to acquire in these under-resourced neighborhoods is likely to severely limit the range of agency the poor can deploy to alleviate their circumstances. Consequently, "(T)he limitations caused by this disconnect from capital-enhancing opportunities deny them the ability to think strategically about ways to transcend poverty. Instead, their lives are predominantly influenced by more constraining institutions that infuse the social and economic rationalities under which they operate" (Quane and Wilson, 2012: p. 2982).

In sum, the cultural milieu of the inner city is embedded in the structural features of concentrated poverty, racial segregation, social isolation, and the lack of neighborhood social organization. Cut off from employment opportunities and trapped in neighborhoods with little access to conventional role models, social networks that contain social capital (e.g., informal job networks), and institutional resources that support families, poor inner-city families face severe obstacles in their efforts to accomplish socially desired ends such as labor force participation and family stability.

The Latino Paradox: Concentrated Inner-City Poverty and the Rise of Latino Immigration

The declining white population in urban areas has had significant implications for the urban tax base as the median household income of blacks and of the growing number of Latinos is significantly below the median income of white households. (According to the US Census Bureau, in 2000 the median annual household income for Latinos was about $14 000 less than that of white households.) Thus, because of the declining tax base and the simultaneous loss of federal funds, many municipalities have experienced difficulty in raising sufficient revenue to cover basic services such as street cleaning, garbage collection, and police protection. Nonetheless, several notable positive developments for inner-city urban areas have accompanied the rise of the immigrant population.

Foreign immigration, especially from Mexico, increased by more than 50% between 1990 and 2000, resulting in a rapid growth in immigrant enclaves in large cities (Sampson, 2012). According to a report by the PEW Hispanic Center, the most significant growth in immigration occurred in the mid-1990s, reaching its peak at the end of the decade (Passel et al., 2012). Although annual immigrant flows from Mexico declined sharply after 2005, in the wake of a weakening US job market and heightened border enforcement, the number

of immigrants from Mexico remains high at approximately 12 million (Passel et al., 2012).

It is noteworthy, as Robert Sampson's (2012) impressive research so clearly reveals, that areas of concentrated immigration are among the safest in the city, and the process of immigrant diffusion revitalized and increased the population of a number of deteriorating inner-city neighborhoods. Sampson states: "Among the public, policy makers, and many academics, a common expectation is that the concentration of immigrants and the influx of foreigners drive up disorder and crime because of the assumed propensities of these groups to commit crimes and settle in poor, presumably disorganized communities … Yet increases in immigration are correlated with less crime, and immigrants appear to be less violent than those born in America, particularly when they live in neighborhoods with high numbers of other immigrants" (Sampson, 2012: p. 252). Immigration has rejuvenated such inner-city neighborhoods as Queens in New York, the Lower West Side of Chicago, pockets of the North and South Sides of Chicago, Bushwick in Brooklyn, and large strips of south central Los Angeles and has lowered their crime rates. "It follows," states Sampson, "that the spatial 'externalities' associated with immigration are multiple in character and constitute a plausible mechanism to explain some of the ecological variation in crime rates of all groups in the host city" (Sampson, 2012: p. 253).

What should be underlined is that although the links between economic hardship and homicide are similar for blacks, Latinos, and Haitians, and although concentrated disadvantaged and neighborhood social processes predict similar patterns of violence across racial and ethnic groups, immigrants tend to be less violent, especially if they reside in concentrated inner-city immigrant enclaves. The research of Morenoff et al. (2001) revealed that residing in a neighborhood of concentrated immigration, even after adjusting for a series of correlated factors such as an individual's immigrant status and poverty, was directly related to lower rates of violence. In short, it appears that immigration is 'protective' against violence.

Moreover, as Sampson points out, increases in immigration are also linked to crime decreases in black inner-city neighborhoods that are proximate to the center of Mexican immigration such as the middle, as well as near southern section of Chicago and the far north-western areas of the city "that have been predominantly white" (Sampson, 2012: p. 255). Sampson hypothesizes that the spillover 'immigration effects' may eventually spread to other Chicago neighborhoods near immigration centers, including the inner-city black neighborhood of Englewood. In Chicago, "crime dropped in the 1990s as immigration surged" (Sampson, 2012: p. 253).

Because immigration results in the spread of diverse and formerly external cultures, this logically implies that the spatial process of diffusion has a cultural overtone. Referring to the subculture of violence in the black inner city depicted in Anderson's 'Code of the Street' (1999) where shared expectations for 'saving face' and demanding respect in the 'street culture' often lead to violent reactions to otherwise petty encounters such as perceived insults and slights, Sampson theorizes that "if one does not share the cultural attribution or perceived meaning of the event, violence is less likely. Outsiders to the culture, that is, are unlikely to be caught in the vicious cycle of interaction (and reaction) that promote violence" (Sampson, 2012: p. 257). In other words, it may be hypothesized that current immigration is resulting in greater perceptibility of competing nonviolent mores that are diffused through social interaction and not only affect immigrant communities, but also depress violent behavior in general.

However, more research is needed on the lasting effects of immigration on crime. Morenoff et al. (2001) found (after accounting for differences in individual, neighborhood, and family background) that first-generation immigrants (those born outside the United States) in Chicago were 45% less likely to commit violent crimes than third-generation Americans. Accordingly, the *Latino paradox* – "whereby Latinos do much better on various social indicators, including violence, than blacks and apparently even whites, given relatively high levels of disadvantaged" (Sampson, 2012: p. 251) – is driven mainly by first-generation immigrants. If the sharp drop in Latino immigration to the United States that began in 2005 represents a long-term rather than a short-term pattern, rates of violence in Latino communities could increase significantly and the structural and related cultural problems that drive high-crime rates in the inner-city African American community could conceivably over time have similar and notable effects in Latino communities, effects that offset the positive impacts of the first generation on inner-city neighborhoods, including their nonviolent mores.

The Inner-City and Public Policy

The prolonged economy recovery of the 1990s provided much hope for poor inner-city residents. Unemployment declined dramatically from 8.6% in 1992 to 5.1% in 1998, and unemployment in the nation's 50 largest cities fell from 8.6% in 1992 to 4.9% in 1998, a decline that exceeded the decreases in unemployment in the cities' surrounding suburbs (U.S. Department of Housing and Urban Development, 1999).

The Great Recession laid waste to many of these impressive gains and many inner-city families that prospered as a result of their hard work in the construction industry and other occupational sectors that surged during the boom are once again finding themselves in dire financial strains. In an effort to blunt some of the misfortune that disproportionately impacts low-income Americans, the Obama Administration's American Recovery and Reinforcement Act included important supports for low-income families. As part of this stimulus package, $80 billion was allocated to extend, among other things, unemployment benefits, temporarily increase the amount of the Earned Income Tax Credit and expand the Supplemental Nutrition Assistance Program (food stamps) for low-income families and children. In addition, the Patient Protection and Affordable Care Act (commonly known as Obamacare) includes provisions that extended health insurance for children to remain covered under their parents'

health insurance plan until they reach the age of 26, which provides needed coverage for young adults in a tight labor market who are unable to find work. Without such coverage, underskilled or undereducated unemployed young adults would have few if any alternatives to accessing quality health services (Wilson, 2013).

However, as the aftershocks of the Great Recession continue to reverberate around the country there is strong evidence that the gains of the 1990s are being eroded for many blacks and Latino families. A recent report by the Pew Charitable Trust estimates that wealth disparities between white households and those of blacks and Latinos are the largest they have been since the government began publishing these figures. The authors remark that "… in percentage terms, the bursting of the housing bubble in 2006 and the recession that followed from late 2007 to mid-2009 took a far greater toll on the wealth of minorities than whites. From 2005 to 2009, inflation-adjusted median wealth fell by 66% among Latino households and 53% among black households, compared with just 16% among white households" (Kochhar et al., 2011: p. 1).

Just a few weeks into the first legislative session of the 113th session of the United States Congress, there is no indication that any new major initiatives are being considered to tackle the declining conditions of the inner-city poor. Indeed, there is no real evidence that a serious attempt to expand employment options for the hundreds of thousands of unemployed and underemployed adults in the country regardless of race, ethnicity, gender, or age is taking shape. Done well and done properly, such efforts should seek to realign the needs of working adults with those of a vastly changing labor market. Adults with a high school diploma or who dropped out of high school face especially onerous challenges to escaping poverty as adults. The abysmal high school dropout rates among blacks and Latinos, especially in the inner city, makes them particularly susceptible to continuing the intergenerational cycle of poverty. Time will tell as to whether a workforce development policy that is serious about meeting the needs of a more specialized labor market with better prepared workers is able to facilitate training and education programs that engage young adults in ways that the formal education system has been unable to do. Similarly, it remains to be seen whether policy makers can work with the business sector to find ways to expand the earning potential of underskilled workers until such time as they can acquire the competencies to be competitive in the labor market. Finding solutions to long-term joblessness and the concentration of poverty in disadvantaged urban areas are not issues that federal, state, or local governments can tackle on their own. Neither can an increasingly specialized workforce be expected to absorb large numbers of low- or unskilled workers, many of whom are also deficient in essential soft skills, which are prerequisites for many employment opportunities. Real and lasting change will require the sort of public–private partnerships that allow for the targeted training of workers to meet the specialized needs of industry. Working together, the public sector can help underwrite the training component and assistance to trainees while they upgrade their skills in the time that the industry can ensure a smooth transition for trained workers into positions where employees' earning potential provides real home for escaping poverty and economic stability.

Abstract

Innovation, and the understanding of processes of innovation, is fundamentally about social, scientific, and economic change. Innovation is seen as underpinning the productivity and success of firms, communities, and nations. Innovation, as a concept, is increasingly considered as a nonlinear multidimensional phenomenon, which involves a complex relational ecosystem with concurrent processes of value cocreation through collaboration. Innovation can be understood on several broad dimensions – product or process; technological or nontechnological; radical or incremental; and open or closed. The article will explore these dimensions, the historical background to innovation, and current issues and challenges with reference to developments in the social, scientific, engineering, and behavioral sciences, including the cross-disciplinary linkages, which illuminate the nature and significance of innovation for the twenty-first century.

Introduction

Innovation, and the understanding of processes of innovation, is fundamentally about social, scientific, and economic change and is underpinned by human experience and action. Writers from Joseph Schumpeter to Thomas Kuhn have described waves of change, where old paradigms and methods are questioned, tested, and creatively destroyed and new ideas, inventions, and innovations emerge.

Over time, the meaning of innovation has itself changed. Originally associated with science and technology, and the new product development approach for commercializing ideas and inventions, innovation increasingly encompasses interactions among institutional, technological, and human systems. Consequently, the understanding of how innovation occurs has also changed from a traditional linear process of invention followed by commercialization to a multidimensional phenomenon involving a complex relational ecosystem with concurrent processes of value cocreation through collaboration, 'design thinking,' and business analytics. George Lakoff and Mark Johnson say that the essence of innovation lies in the normal pattern of everyday life embodied in the experience of individuals, across cultures and domains (Lakoff and Johnson, 2009).

Innovation is now broadly defined by governments, firms, and international organizations as the mechanism by which economic performance can be improved, and even transformed, and social progress achieved. It is a significant part of the strategy and rhetoric of many organizations, cutting across disciplines and specializations, and is seen as a key not only to increasing productivity and competitiveness, but also to driving environmental sustainability and social inclusion. Managers and organizations increasingly engage in innovation 'ecosystems,' investing both in the tangible aspects of innovation, most notably technological research and development (R&D), and in more intangible aspects, such as social capital, knowledge creation, application and dissemination, systems integration, and business model design. The interaction of these organizations, within markets, with research and educational institutions and public funding agencies has evolved into local and national systems of innovation, with Freeman (1982) and Nelson and Winter (1982) among the first to conceptualize the development of these national systems.

In the context of unprecedented technological advancement, demographic change, environmental pressures, and globalization, this article will provide an updated taxonomy of innovation concepts and practice, with an emphasis on the role of management and organizations, to illuminate the nature and significance of innovation for the twenty-first century. The historical background to innovation, common types of innovation, and current issues and challenges in the management of innovation will be explored with reference to developments in the social, scientific, engineering, and behavioral sciences, including cross-disciplinary linkages.

History

Some of the oldest innovations stretch back to prehistoric times when innovation was closely linked to survival and adaptation. Innovation can be detected in the cave paintings in the Chauvet Cave in France, arguably a precursor to the innovation of filmic representational processes. The paintings, some dating back 35 000 years, depict a number of animals through a technique employing subtle shading and an attempt at perspective. Filmmaker Werner Herzog, in his three-dimensional documentary *Cave of Forgotten Dreams* (2011), conjectures that the paintings, with their attempt at capturing movement with light, prefigure the creation of cinema. The style of the painting was developed by incorporating the shape and texture of the cave's walls to create a sense of movement in conjunction with a flickering light from fire. This exemplifies a characteristic of innovation – it can be a slow and continuously progressed idea, which evolves and takes a final form over time. Even in the contemporary context, film is continuously advanced through new technologies and techniques heightening the filmic experience, while simultaneously transforming the industries around it.

Definition

Innovation is broadly defined as 'an idea, practice, or object that is perceived as new by an individual or other unit of adoption' (Rogers, 2001: 7540). It can apply to any phenomenon (material and immaterial) developed by an individual/collective that is in itself a catalyst for improvement in any area of life. The term 'innovation' when entered in Google currently brings up over 400 million hits. This is ever increasing, with the concept of innovation becoming more pervasive in all aspects of social and behavioral sciences.

Over time, the definition of innovation has widened significantly; originally associated with science and technology and the new product-development approach for commercializing ideas and inventions, innovation increasingly encompasses interactions among technological and human systems that lead to managerial and organizational change. The definition of innovation in the 2005 Oslo Manual as 'the implementation of a new or significantly improved product (good or service), or process, a new marketing method, or a new organizational method in business practices, workplace organization or external relations' is still relevant and valid. Paul Trott (2012) adds a further dimension – innovation as an integrated management process of idea generation, technology development, knowledge application, and commercial exploitation to create a new (or improved) product, process, service, or organizational change.

Innovation is inherently connected to broad social, scientific, and economic changes. Joseph Schumpeter was an early writer on innovation, exploring large-scale change through economics. Originally used by Marx, the term 'creative destruction' was further developed by Schumpeter to describe how the creation of new modes of production destroyed existing modes that had themselves been the result of past innovations. That is, over time one can observe innovation as waves of change. Schumpeter saw technological competition (where successful innovators spurred imitators) as a way to understand economic development. In his work *Capitalism, Socialism and Democracy*, he proposed that large firms with monopoly power were necessary to support innovation, in part a reflection of the transformations that had occurred in the American economy (Schumpeter, 1942).

These broader waves of growth cycles or technological development in Western societies were also termed the 'Kondratieff waves.' They follow the sequence of early mechanization (1770s–80s), steam power and railways (1830s–40s), electrical and heavy engineering (1880s–90s), automobile production (1930s–40s), and information and communication (1980s–90s), extending into the present-day information revolution. Each of these waves of innovation was accompanied by the growth of specific industries led by different countries, in turn leading to global economic shifts over time. For example, while the first wave was led by Britain, France, and Belgium, the second wave was propelled by the United States and Germany, and the final wave is being driven by Asian countries – Taiwan, Korea, Japan, etc. (Trott, 2012). These waves of change are also reflected in Thomas Kuhn's *The Structure of Scientific Revolutions*, which describes knowledge production in terms of paradigm shifts, where sets of understandings, assumptions, and knowledge are created, established, and then eventually displaced by new paradigms (Kuhn, 1962).

This historical brief highlights the heterogeneity of the innovation process across time, across sectors, and across countries, and shows that, although innovation is closely associated with 'invention,' it is much more than invention – it occurs not just in laboratories and universities but across society and the workforce. There is a conceptual interdependence between innovation and invention and 'time lag' is one of the major factors that differentiate the two concepts. Invention is a first occurrence of an idea, and is often associated with technical developments and novelty. Innovation, while it may include technical/technological and nontechnological change, it also involves a broader process that leads to the diffusion and adoption of an invention in practice. Innovation is challenging, and being a 'first mover' does not necessarily secure a strategic position or guarantee success.

From Linear to Open

Innovation has been historically conceptualized as a linear process of development, associated with new product development, and the activity to take it to market. In such models, innovation goes through a series of processes/stages such as research, or a scientific basis, for the innovation, development, production, and marketing. This linear approach leads to an assumption of a generalized chain of causation, and neglects the multiple feedback loops and iterations that occur during the evolution of an invention or innovation.

Although most innovations stem from scientific breakthroughs, this is not always true. An organization's ability to review and combine new and existing knowledge, as well as its ability to interact with external parties, has led to innovation, more recently being considered as an open process, with complex and integrative relationships between consumer, product, firm, and market. In this way, organizational boundaries are porous and firms must leverage outside expertise, and the insights of consumers, in developing new products and services.

The Diffusion of Innovation

The diffusion of innovation, looking at how new products, services, and ideas spread, has long been a topic of research across both the social sciences and natural sciences. The cumulative adoption of innovation (of any type) over time generally follows an S-shaped curve as the product moves through its life cycle. Everett Rogers classified consumers, as a group of adopters based on their demographic and psychographic features, into five segments – innovators, early adopters, early majority, late majority, and laggards, according to how they successively adopted the innovation through the stages of the product life cycle (Rogers, 1995).

Geoffrey Moore extends this by classifying adopters as technology enthusiasts, visionaries, pragmatists, conservatives, and sceptics, who sequentially adopt the innovation as the product life cycle progresses (Moore, 2004). Ordinarily, the rate of adoption of radically new products, services, and ideas is impeded by consumer unfamiliarity and uncertainty.

The Systemic Nature of Innovation

The extent to which innovation is developed and sustained within organizations is contingent upon the external business environment and, in turn, the wider economic, social, and political context in which the organizations operate. Increased importance is placed on defining the linkages between the innovation processes within organizations and the wider system with which these processes are integrated. The systemic frameworks of innovation that have emerged are embedded in the technological, institutional, infrastructural, and economic realms (Freeman and Soete, 1997).

Innovation systems also operate on sectoral, regional, and national levels. In sectoral systems of innovation, organizations belonging to a particular sector engage in innovation through collaborative networks, and leveraging sectoral knowledge and technologies. Regional systems focus on territorial-based innovation systems, leveraging the success of regional clusters and industrial districts, while national systems emphasize interlinked political, economic, social, and cultural factors within a country (Lundvall, 1992). These three perspectives – national, sectoral, and regional – are variants of systems of innovation.

For organizational managers, and policy-makers, the finance, technology, and infrastructure requirements of the innovation system, and the complementarities that exist between these, are crucial. Private and public sector agents such as government bodies, and educational and research institutions, play a critical role in ensuring that innovation systems are supported by the right mix of technological, social, and economic infrastructure.

Types of Innovation

The phenomenon of innovation has historically brought change and transformation. Today, innovation is increasingly seen through a cross-disciplinary lens spanning engineering, economics, sociology, organizational science, and management perspectives.

Product or Process Innovation

Joseph Schumpeter was among the first to classify innovation into five different types: new products, new methods of production or transportation, new sources of supply, new markets, and new ways of organizing business (Schumpeter, 1942). Earlier research on innovation focused on the first two of these: product innovation and process innovation. Product innovation concentrates on the development of new or improved products and services, for example, the introduction by Apple Inc. of the iPod and iPad. Process innovation, on the other hand, involves the development of new ways of producing products and services, for example, lean manufacturing methods, just-in-time (JIT) manufacturing systems, and quality circles.

Technological or Nontechnological Innovation

While the distinction between product and process innovation is useful, the classification of innovation as 'technological innovation' and 'nontechnological innovation' is more relevant to recent developments. Technological innovation involves new or improved technology, for example, new types of machinery, while nontechnological innovation finds new ways of producing, distributing, or organizing work. Nontechnological innovation is associated with organizational innovations such as new or improved organizational structures, systems, or processes. Examples of nontechnological organizational innovations include total quality management, Six Sigma, and business process reengineering.

Business model innovation is a form of organizational innovation where businesses create innovative ways to create and deliver value to their stakeholders. Accordingly, management innovation has been expressed as "*invention and implementation of a management practice, process, structure, or technique that is new to the state of the art and is intended to further organisational goals*" (Birkinshaw et al., 2008: 825). IKEA and Dell are business model innovators who have fundamentally changed the structures and dynamics of their respective industries. IKEA cocreates value with its customers by outsourcing the transport and assembly of products to them. Dell, on the other hand, has innovated its supply chain by eliminating distributors, and instead moved to assembling-to-order, which allows the customization and personalization of products to individual customer needs.

Incremental or Radical Innovation

Innovation can also be categorized as incremental or radical based on how revolutionary and ground-breaking it is (Freeman and Soete, 1997; Christensen, 2003). Incremental innovations are continuous improvements that incrementally change existing products or services, and are regarded as 'sustaining innovations.' Radical innovations, on the other hand, are discontinuous, path-breaking changes that have far-reaching impacts, and often transform the face of the industry and marketplace. Examples of such radical innovations include online music downloads (disrupting CDs), digital film (disrupting photographic film), online news platforms (disrupting traditional newspapers), and online shopping (disrupting the brick-and-mortar models in the retail industry). Such innovations are also referred to as 'disruptive innovations' and can be equated to Schumpeter's concept of creative destruction.

Open or Closed Innovation

Innovation can be open or closed depending on the extent to which the organization interacts with its environment. Historically innovations were mainly closed, involving little communication or collaboration with entities outside of the organization. Today's highly networked, knowledge-based economy increasingly requires open innovations where the innovation activities involve knowledge exchange with external entities, in particular, across the organization's supply chain (Chesborough, 2003). Open innovation leverages external relationships and collaborations to enhance systemic knowledge-sharing and drives innovation outcomes.

User-Led Innovation and Service Innovation

Service innovation is a type of open innovation gaining prominence in recent times. With the growing economic importance of the services sector, service innovation is playing an ever more significant role in driving growth in today's knowledge-intensive economy. This type of innovation responds to increased customer input, interactivity, and specialization; is multidimensional in nature; and includes strategic, productivity, and performance dimensions. Services with higher interactivity with customers provide increased opportunities for innovation through interactions involving enhanced knowledge-sharing and learning processes, and it is these higher-order capabilities that contribute to innovation in services. Examples include Apple's development of the app resulting in value cocreation, and the development in Australia of a virtual critical care unit for patients receiving emergency care in remote locations through real-time digital telehealth.

The Innovation Life Cycle

Innovation opportunities change over time, and the most important innovations are often based on the life cycle of an industry or product. These innovations can involve changes that totally transform economic value. Mature industries tend to focus on product innovation or repositioning their existing products, while newer industry sectors, such as biotech or nanomaterials, have scope to experiment with new product or service concepts. The innovation life cycle has three sequential phases: fluid, transitional, and specific. The fluid phase is characterized by radical product innovation, the transitional phase involves process innovation, and the final specific phase comprises incremental innovation (Abernathy and Utterback, 1978).

Management of Innovation

At the organizational level, the management of innovation is critical to develop and foster sustained innovation as a driver of long-term survival, and a sustainable competitive advantage. Innovation can be managed and facilitated through organizational structure, strategy, processes, leadership and culture, and the connection of these elements to organizational performance.

Structure

Management of innovation in organizations involves the constant pressure to strike a balance between the stable, efficiency-seeking routines of day-to-day operations and the dynamic, creativity-seeking routines that promote innovation. Organizations need to be ambidextrous in order to simultaneously engage in both exploitation – focusing on control, efficiency and productivity, and exploration – embracing creativity, search, and discovery. One way to do this is to design organizational structures with separate subunits focusing on exploration and exploitation as well as internally aligning systems, processes, and cultures to effectively foster both explorative and exploitative activities (O'Reilly and Tushman, 2008). Organizations can cultivate weak ties with some network partners and strong ties with other partners, and this can create a balance between novelty and reliability in innovation processes.

Earlier theories argue that 'organic' structures, which are generally more decentralized, less formalized, and more flexible, are more capable of facilitating innovation compared to 'mechanistic' structures that are more centralized, formalized, and rigid. A network model is another structure that supports openness and communication among partners; and organizational structures that facilitate informal and formal networking, as well as lateral communication and knowledge-sharing can also foster creativity.

Strategy

Two general schools of strategy have implications for the management of innovation: the market-based view and the resource-based view. According to the market-based view, the drivers and inhibitors of innovation within an organization are contingent on external market conditions and innovation is dependent on firms' success in exploiting opportunities in the marketplace. The resource-based view sees the presence of valuable, rare, inimitable, and nonsubstitutable resources and capabilities within an organization as the basis for a sustainable competitive advantage built on enhanced innovation performance (Prahalad and Hamel, 1990). The dynamic capabilities approach is an extension of the resource-based view and contends that firms need to constantly align, modify, and reconfigure their resources and capabilities in a dynamic and volatile environment to ensure sustained innovation and earnings above normal returns (Teece, 2009).

Knowledge Management Processes

The early linear models of innovation mainly focused on the role of technology in stimulating innovation, and then included the role of the marketplace and customer interactions as key to the innovation process. It was not until later that the role of knowledge as a conduit between all stages of innovation, starting from idea generation to commercialization of innovation, was recognized. Terms like 'architecture knowledge' explain how technological knowledge is integrated as a central process in fostering innovation. Different aspects of organizational learning also play into knowledge creation, which in turn feeds into innovation processes. How effective this knowledge acquisition and assimilation is, will impact on knowledge exploitation, a critical component for generating innovative output. Technology also assists in this, enabling better information flow and knowledge exchange, and driving innovation through facilitation of creativity, communication, and operational improvement processes.

Leadership and Organizational Culture

Organizational managers recognize that, in managing innovation, traditional management approaches need to be reframed to address the dynamic, networked, and complex nature of innovation processes. Empowered cross-functional teams, and shared leadership, creates the necessary environment for

innovation to flourish. Innovation in organizations is also more likely to be supported where the leadership is more open to new ideas and solutions. All cultures are dynamic and continuously evolving. Organizational culture is no different, and workplace cultures should reflect this through: fostering employee involvement in decision-making processes, promoting openness to learning and change, and being responsive to customer and stakeholder needs. This is likely lead to an organization's superior innovation performance and advantage over its peers.

Measuring Innovation

Innovation, by definition, involves novelty and includes both the creation of new knowledge and the reinterpretation and application of existing knowledge. This makes innovation inherently difficult to quantify and measure. Indicators such as the European Community Innovation Survey (CIS) are centered on innovation inputs and outputs and produce national measures that have some degree of international comparability. Major indicators used to measure innovation include data on R&D, patent applications and grants, scientific publications and citations (bibliometric data), and technical performance characteristics (technometric data).

CIS works well for manufacturers, but not for the heterogeneous services sector, and its associated intangible inputs and outputs. In response, a framework of seven innovation management measurement has been developed. They are inputs, knowledge management, innovation strategy, organizational culture, portfolio management, project management, and commercialization. Devising metrics to quantify intangible elements involves a multiindicator approach that integrates multiple data sources on innovation activities. These may comprise resources (people and ideas), efforts (measured by innovation expenditure of various sorts), innovation outputs (innovation outcomes including numbers of patents), and performance (including the percentage of sales due to new products and services). These measure innovation on a holistic basis. One problem with this approach, however, is that it does not necessarily encompass services, managerial, and open innovations centered on social and human elements.

National Systems of Innovation

At the heart of any national innovation system is the interaction of organizations with other organizations in the value network, such as suppliers, competitors, and customers. Other networks of institutions including universities, and government and public agencies are also embodied in the system. A national system of innovation includes all economic, social, political, and institutional factors impacting on the development and diffusion of innovations, both nationally and globally.

Innovation is a driver of economic growth and productivity. It evolves out of a mixture of activities, and is influenced by framework conditions but these are not globally uniform. There are big variations in the performance of nations linked to the characteristics of their innovation systems. Nations have different levels of direct investment in R&D and indirect investment in other mechanisms such as tax benefits, subsidies, and incentives for collaboration, skills and education levels, and national policy decisions, all of which act as crucial stimulants for innovation. National systems of innovation seek to provide a well-coordinated governance framework for achieving congenial national conditions that foster innovation as a means of sustaining long-term economic growth. National governments, from a range of countries including Australia, Japan, India, the United States and the UK, and international organizations such as the OECD and the UNCTAD, use policy-making instruments to orient innovation systems toward enhancing innovative performance in national economies. In some countries, for example, educational institutions such as universities drive R&D, while in others, independent research institutes are the key R&D performers.

Emerging Directions and Challenges

Innovation is now viewed via a cross-disciplinary approach, including economics, cognitive sciences, sociology, organizational science, and management and business studies.

Technological Directions

As we move forward into the twenty-first century, the concept of cloud computing is a recent disruptive innovation providing a platform for many innovations in the future. It has the potential to be the next major driver of business model innovation. In the new paradigm of cloud computing, there is an intersection of technology as a complex conglomeration of products and services is offered as a utility, rather than a service. It harnesses various aspects and modes of technology such as social and business networking sites, and personal digital/computer products/applications such as smart phones, e-mail, tablets, etc. Cloud computing requires minimal management by service providers and gives 24-hour access anywhere to personal data and computer resources held remotely.

In effect, this innovation empowers the end user to be free of dependency on software applications and the more prosaic aspects of computer and digital device use. The innovative aspects of cloud computing encapsulate recent developments and implementations of computer-based services and applications, and their use. It is a paradigm shift in the way technology is used and will have a far-reaching impact into the twenty-first century. The ability to capitalize on this technology into the future will depend on how cultural differences affect the likelihood, and pace, of business and IT cloud service adoption.

The New Face of Manufacturing

Additive manufacturing is a process of manufacturing that signals a major shift in the way products are created. It can be defined as technologies linked to a type of manufacturing embracing key elements of digital technology, computer-aided design, and three-dimensional modeling information, in order to create products through a layering of material using innovative manufacturing techniques. Additive manufacturing will be highly relevant to future improvements in medical and dental technologies, and many other areas where creating

tailor-made products will provide precision and convenience. The future directions for this type of technology include the notion of a 'desktop factory'; this has already begun to take place with the sale of three-dimensional printers released in the market since 2010. This makes additive manufacturing a new frontier for the development of prototypes, models, and items for various purposes ranging from engineering and industrial to personal needs, and encompassing functional aspects as well as the area of entertainment. The traditional manufacturing approach of keeping the customer removed from the operation is not possible, or appropriate, for service organizations. The servitization of the manufacturing industry, and the bundling of services with products, has blurred the distinction between product and service. Technological advancements, and increasing globalization, have pushed value cocreation; and open innovation, as a result of customer participation, has prompted business model, social, and service innovations.

Design and Integrative Thinking

In response to 'wicked problems,' a category of problem that cannot be singularly defined nor solved, innovators are turning to new ways of problem-solving that are far different from the traditional methods of rational, linear-based methods. Design thinking is one such alternative method, which encompasses the unwrapping of complex problem-solving processes – it is a user-centered and iterative approach focused on the solution, rather than the problem. It has application for both policy-makers and organizations. Traditional ways of running companies/firms are no longer adequate for the twenty-first century, and it is increasingly recognized that integrative thinking is essential for all organizations. Integrative thinking involves principles of design thinking being ingrained in the innovation processes that are adopted. This engenders a mind-set of creative thinking-in-action and fosters a creative and human-centered organizational culture.

Implications for Teaching Innovation/Management Education

The assumption that organizations, their behavior, culture, values and doctrines, and management are central to stimulating innovation highlights the role of management education and business schools. The increasing importance of human capital in innovation means the role of management education, and in particular, the way business schools might better develop management competencies and attributes, is crucial in fostering innovation.

The recent work on management education by Datar et al. (2010) reviewed a number of leading North American and European business schools and identified unmet needs relating to 'knowing' (identify, analyze, explain), 'doing' (learn skills needed), and 'being' (deeper psychological understanding of self). Management innovation needs to innovate and change future educational approaches and outcomes. The emergence of design and integrative thinking for business and management, and the necessity to solve 'wicked problems,' creates an essential need to build innovation capability in organizations. More broadly, there is a challenge globally for policy-makers and organizations alike to draw on the talent and creativity of workforces to innovate our approaches to value creation, economic efficiency, environmental sustainability, and social progress.

Conclusion

Innovation, as a concept, is increasingly considered as a nonlinear multidimensional phenomenon, which profoundly affects us. Despite its significance, the challenges of innovation are immense. Organizations rarely innovate alone: increasingly, innovation involves a complex relational ecosystem with concurrent processes of value cocreation through collaboration. Innovation can be understood on several broad dimensions – product or process; technological or nontechnological; radical or incremental; and open or closed. Innovation is a relentless process of change and improvement that is inevitably characterized by successes and failures; and its outcomes are always uncertain. Nevertheless, the importance of innovation is clear, not only in driving the growth and profitability of individual enterprises, but also in realizing the social and productive potential of nations and communities.

Abstract

In this article, the theoretical and empirical literature on the employment impact of technological change is critically discussed, the relative explanatory power of the competing theories is compared and the macro-, sectoral, and microevidence on the issue is detailed.

Introduction

Historically, the fear of technological unemployment has always emerged in ages characterized by radical technological changes. For instance, the striking response of the English workers to the first industrial revolution was the destruction of machines under the charismatic leadership of Ned Ludd in the industrial areas and of Captain Swing in the countryside (see Hobsbawm, 1968; Hobsbawm and Rudé, 1969).

On the other hand, since its very beginning, the economic theory has pointed out the existence of economic forces which can spontaneously compensate for the reduction in employment due to technological progress. It is interesting that nowadays – *mutatis mutandis* – the present economic debate about the employment impact of innovation is still characterized by a focus on those market compensation forces which can counterbalance the initial labor-saving effect of process innovation.

In this article, the theoretical and empirical literature on the employment impact of technological change will be critically discussed, the relative explanatory power of the competing theories will be compared and the macro- and microevidence on the issue will be detailed.

In particular, the next section will be devoted to the so-called 'theory of compensation,' a classical theory which is still the basis of current economic models which try to understand the employment impact of innovation. In the light of the classical taxonomy, Section Innovation and Employment: the Empirical Evidence will present a survey of the available empirical evidence on the relationship between innovation and employment both at the macro-, sectoral, and microlevel. Section Conclusion will briefly conclude.

The Theory

By definition, technological change allows to produce the same amount of goods with a lower amount of production factors, namely capital and labor. However, this is only the 'direct' effect of technological change, and particularly of process innovation. Indeed, the economic discipline – since its foundation – has tried to dispel the concerns about the direct harmful effects of technological change pointing out both the market mechanisms able to counterbalance the direct impact of process innovation and the job-creating effects of product innovation.

Thus, in the first half of the nineteenth century – while the Luddites were destroying the new machines – economists put forward a theory that Marx later called the 'compensation theory' (see Marx, 1961: vol. 1, Chap. 13, 1969: Chap. 18). This theory is made up of different market compensation mechanisms which are triggered by technical change itself and which can counterbalance the initial labor-saving impact of process innovation (for an extensive analysis, see also Vivarelli, 1995: Chaps 2 and 3; Petit, 1995; Vivarelli and Pianta, 2000: Chap. 2; Pianta, 2005).

1. The compensation mechanism 'via new machines.'

The same process innovations, which displace workers in the user industries, create new jobs in the capital sectors where the new machines are produced (see, for instance, Say, 1964).

2. The compensation mechanism 'via decrease in prices.'

On the one hand, process innovations involve the displacement of workers; on the other hand, these innovations themselves lead to a decrease in the unit costs of production and – in a competitive market – this effect is translated into decreasing prices; in turn, decreasing prices stimulate a new demand for products and so additional production and employment.

Indeed, the compensation mechanism 'via decrease in prices' has been often reproposed in the history of economic thought both by neoclassical economists at the beginning of this century (see Clark, 1907: p. 270; Pigou, 1962: p. 672) and by modern theorists (see Heffernan, 1981; Neary, 1981; Stoneman, 1983a: Chaps 11 and 12; Hall and Heffernan, 1985; Dobbs et al., 1987; Nickell and Kong, 1989; for a detailed analysis of the hypotheses, procedures and conclusions of these models, see Vivarelli, 1995: Chaps 4 and 6).

3. The compensation mechanism 'via new investments.'

In a world where the competitive convergence is not instantaneous, it is observed that during the gap between the decrease in costs – due to technical progress – and the consequent fall in prices, extraprofits may be accumulated by the innovative entrepreneurs. These profits are invested and so new productions and new jobs are created. Originally put forward by Ricardo (1951: vol. I, third ed. 1821), this proposition has also been called forth by marginalist economists like Marshall (1961: p. 542) and Douglas (1930: p. 936) and by recent dynamic models such as those by Hicks (1973) and Stoneman (1983a: pp. 177–181, 1983b).

 http://dx.doi.org/10.1016/B978-0-08-097086-8.94010-8

4. The compensation mechanism 'via decrease in wages.'

As with other forms of unemployment, the direct effect of labor-saving technologies may be compensated within the labor market through a proper price adjustment. In a neoclassical framework – with free competition and full substitutability between labor and capital – a decrease in wages leads to an increase in the demand for labor. The first to apply this kind of argument to the specific case of technological unemployment was Wicksell (1961: p. 137), followed by Hicks (1932: p. 56), Pigou (1933: p. 256) and Robbins (1934: p. 186).

In modern times, the wage adjustment is a component of partial equilibrium models such as those by Neary (1981) and Sinclair (1981) and generally equilibrium analyses such as those by Layard and Nickell (1985), Venables (1985) and Layard et al. (1991, 1994).

5. The compensation mechanism 'via increase in incomes.'

Directly in contrast with the previous one, this compensation mechanism has been put forward by the Keynesian and Kaldorian tradition. In a Fordist mode of production, unions take part in the distribution of the fruits of technical progress. So it has to be taken into account that a portion of the cost savings due to technical change can be translated into higher income and hence higher consumption. This increase in demand leads to an increase in employment which may compensate the initial job losses due to process innovations (see Pasinetti, 1981; Boyer, 1988a,b, 1990).

6. The compensation mechanism 'via new products.'

Technical change is not equivalent to process innovation, but it can assume the form of creation and commercialization of new products; in this case, new economic branches develop and additional jobs are created. Once again, the labor-intensive impact of product innovations was underlined by classical economists (Say, 1964: p. 88) and even the most severe critic of compensation theory admitted the positive employment benefits that can derive from this kind of technical progress (Marx, 1961: vol. 1, p. 445).

In the current debate, various studies (Freeman et al., 1982; Freeman and Soete, 1987, 1994; Vivarelli and Pianta, 2000; Edquist et al., 2001) agree that product innovations have a positive impact on employment since they open the way to the development of either entire new goods or main differentiation of mature goods. In the latter case, the 'welfare effect' (new branches of production) has to be compared with the 'substitution effect' (displacement of mature products; see Katsoulacos, 1984, 1986).

On the whole, economic theory clarifies those market forces which can potentially counterbalance the initial labor-saving impact of process innovation; moreover, it is recognized that the alternative form of technological change – namely the diffusion of entirely new products – can imply an obvious job-creating effect.

On the other hand, compensation mechanisms can be hindered – or even annihilated – by the existence of important drawbacks. Using the same taxonomy which has been proposed above, the main criticisms of the compensation theory can be singled out as follows.

1. With few exceptions (see Hicks, 1973), nowadays this compensation mechanism is not put forward anymore. Indeed, Marx's critique of this mechanism was so sharp that it stopped this first line of reasoning of the compensation theory: he pointed out that a machine can only be employed profitably if it is the outcome of far fewer men than it replaces (Marx, 1969: p. 552).

Moreover, labor-saving technologies spread around in the capital goods sector, as well; so this compensation is an endless story which can be only partial (Marx, 1969: p. 551).

Finally, the new machines can be implemented either through additional investments (see point C) or simply by substitution of the obsolete ones (scrapping). In the latter case – which is indeed the most frequent one – there is no compensation at all (see, for instance, Freeman et al., 1982).

2. As originally noted by Malthus (1964: vol. II, pp. 551–560) and Sismondi (1971: p. 284), the very first effect of labor-saving process innovation is a decrease in the aggregate demand due to the cessation of the demand previously associated with the dismissed workers. So, the mechanism 'via decrease in prices' deals with a decreased demand and has to more than counterbalance the initial decrease in the aggregate purchasing power.

In addition, this mechanism relies on Say's law and does not take into account that demand constraints might occur. Difficulties concerning the components of the 'effective demand' – in Keynes' terms – such as a low value of the 'marginal efficiency of capital' (see Keynes, 1973: Chap. 11) can involve a delay in expenditure decisions and a lower demand elasticity. If such is the case, this compensation mechanism is hindered and technological unemployment ceases to be a temporary problem (for a detailed criticism about compensation based on Say's law, see also Standing, 1984: pp. 131–133).

Finally, the effectiveness of the mechanism 'via decrease in prices' depends on the hypothesis of perfect competition. If an oligopolistic regime is dominant, the whole compensation is strongly weakened since cost savings are not necessarily and entirely translated into decreasing prices (see Sylos Labini, 1969: p. 160).

3. Also the compensation mechanism 'via new investments' relies on the Say's law assumption that the accumulated profits due to technical change are entirely and immediately translated into additional investments. Again, Marx's and Keynes's treatment of Say's law can be used to argue against the full effectiveness of this compensation mechanism. In other words, the theoretical analysis has to take into account the 'animal spirits' and the economic agents' expectations, which can delay the translation of additional profits into 'effective demand' (see Pasinetti, 1981; Freeman and Soete, 1987; Vivarelli, 1995; Appelbaum and Schettkat, 1995; Pianta, 2005).

Moreover, the intrinsic nature of the new investments does matter; if these are capital-intensive, compensation can only be partial (Marx, 1961: vol. I, p. 628).

4. Also the mechanism 'via decrease in wages' collides with the Keynesian theory of effective demand. On the one hand, a decrease in wages can induce firms to hire additional

workers, but – on the other hand – the decreased aggregate demand lowers the employers' expectations and so they tend to hire less workers.

A second criticism can be launched to this mechanism if the cumulative and irreversible nature of modern technical change is properly taken into account (see Rosenberg, 1976; Dosi, 1988). In this view, science and technology have their own rules: along a 'technological trajectory,' 'localized technical progress' occurs and this can give rise to 'locked in' technologies (see Stiglitz, 1987: p. 128; Freeman and Soete, 1987: p. 42). If the cumulative and localized nature of technical change is taken into account, the hypothesis of perfect substitutability between capital and labor assumed by neoclassical models appears to be quite arbitrary (Freeman and Soete, 1987: p. 46).

5. During the 'golden age' of the 1950s and 1960s the Fordist mode of production was based on a relevant change in the labor-wage nexus. Instead of leaving the wage to be regulated by a competitive labor-market, workers were allowed to take possession of a relevant portion of productivity gains due to technical progress. In turn, the increased real wages involved mass consumption and this stimulated investments leading to further productivity gains through technical progress and scale economies (Boyer, 1988c,d). Labor-saving technologies were introduced on large scale, but the Kaldorian 'virtuous circle' allowed an important compensation 'via new incomes.'

Nowadays, the Fordist mode of production is over for many reasons that cannot be discussed here (see Boyer, 1988c, 1990). The distribution of income follows different rules and the labor market has returned to be competitive. On the whole, this compensation mechanism has been strongly weakened in the new institutional context.

6. New products are still the more powerful way to counterbalance labor-saving process innovations. Yet, different 'technological paradigms' (see Dosi, 1982) are characterized by different clusters of new products which in turn have very different impacts on employment. So, the introduction of the automobile had a much higher labor-intensive effect than the diffusion of the home computers. As a matter of fact, in different historical periods and different institutional frameworks, the relative balance between the labor-saving effect of process innovations and the labor-intensive impact of product innovations can considerably vary.

In conclusion, the relationship between innovation and employment can be represented by a very complex picture where the direct labor-saving impact of process innovation, the compensation mechanisms, the drawbacks and hindrances which can severely weaken the effectiveness of such mechanisms and the labor-friendly nature of product innovation can combine in very diverse outcomes.

While the 'end of work' popular approach (see Rifkin, 1995) erroneously underestimates the opportunities for compensation, economists sometimes forget that compensation can only be partial and that it is dependent on particular historical and institutional circumstances.

Indeed, as it emerges from whatever has been discussed so far, economic theory does not have a clear-cut answer about the employment effect of innovation; then, attention should be turned to aggregate, sectoral and microeconomic empirical analyses which should take into account the different forms of technical change, their direct effects on labor, the various compensation mechanisms and the possible hindrances to these mechanisms.

Innovation and Employment: The Empirical Evidence

Whilst theoretical economists may develop clear models about the employment impact of process and product innovation, applied economists have 'to measure' process and product innovation, the compensation mechanisms and the final employment impact of innovation; from this respect, at least three main problems arise.

First, innovation is difficult to measure; traditional indicators such as R&D (input indicator), patents, and relevant innovation (output indicators) are seldom fully available and are often inadequate to fully represent technological progress. For instance, most of process innovation is implemented through 'embodied technological change' (ETC) (The embodied nature of technological progress and the effects related to its spread in the economy were originally discussed by Salter (1960) and Solow (1960) who underlined that technological progress might be incorporated in new vintages of capital introduced either through additional investment or simply by scrapping.), in turn introduced through gross investment. This technological input is often more important than R&D activities: think for instance to traditional sectors and to the Small and Medium Enterprises (SMEs), where in-house R&D has a very limited role and conversely most of innovation is introduced through the acquisition of capital goods. In terms of Pavitt (1984) taxonomy, technological change in the 'supplier-dominated' firms is much more dependent on machineries acquired by the 'specialized suppliers' than from their own R&D expenditures.

R&D and ETC can be considered the two faces of innovation, with R&D mainly correlated with the labor-friendly product innovation and ETC mainly related to the labor-saving process innovation. Indeed, recent microeconometric studies – using data from the European Community Innovation Surveys (CIS) – have confirmed empirically how R&D expenditures are closely linked with product innovation, while innovative investment (especially devoted to new machinery and equipment incorporating ETC) turns out to be related to process innovation (see Conte and Vivarelli, 2005; Parisi et al., 2006).

Second, as discussed in Section The Theory, the final employment impact of innovation depends on institutional mechanisms which can be very different at the micro-, meso-, and macrolevel and can vary in different economic contexts, such as in different countries or in different sectors within the same country. For instance, a different degree of enforcement in the intellectual property rights (IPRs) can induce a different balance in the distribution between R&D and ETC and consequently can imply different employment outcomes.

Third, it is difficult to distinguish the final impact of innovation on employment, since the latter is influenced by many other factors: namely, the macroeconomic and cyclical

conditions, the labor-market dynamics, the trends in working time, and so on.

The macroeconomic empirical analyses of the relationship between innovation and employment are largely affected by the three methodological problems discussed above. While they are attractive, since they can take into account all the direct and indirect effects of innovation (see previous section), they are often severely constrained by the difficulty to find a proper aggregate proxy of technological change and by the fact that the final employment national trend is codetermined by overwhelming institutional and macroeconomic determinants difficult to control for.

Although to a lesser extent, these considerations also apply when empirical analysis is carried out at the sectoral level. Moreover, sectoral analysis can be affected by either a negative or a positive bias according to the observation point of view (manufacturing versus services).

In this context, microeconometric studies have the great advantage to allow a direct and precise firm level mapping of innovation variables, both in terms of inputs and outputs. Indeed, only firm-level data can account for R&D expenditures, capital formation, product and process innovation, and directly relate them to the firm's employment trend. In other words, only the microeconometric empirical analysis can grasp the very nature of firms' innovative activities and throws some light on the actual ways how new products may generate new jobs and labor-saving process innovation may destroy old ones.

Obviously, the need for the microeconometric analysis should also take into account important limitations of firm-level data. First, the microeconomic approach cannot take fully into account the indirect compensation effects (see Section The Theory) which operate not only at the level of the firm but also through intersectoral linkages and aggregate dynamics. Second, a possible shortcoming of this kind of analysis consists in a 'positive bias' which tends to underline the positive employment consequences of innovation. In fact, once the empirical analysis is developed at the level of the single firm, innovative firms tend to be characterized by the better employment performances since they gain market shares because of innovation. Even when the innovation is labor-saving, microeconomic analyses generally show a positive link between technology and employment since they do not take into account the important effect on the rivals, which are crowded out by the innovative firms (this is the so-called 'business stealing' effect; see Section Microeconomic Empirical Evidence below).

Keeping these methodological remarks in mind, now attention can be turned to the single levels of the empirical analysis of the relationship between technology and employment; consistently with whatever has been discussed so far, the macroeconomic and the sectoral studies will be briefly surveyed, while a more detailed attention will be devoted to the microeconometric literature.

Aggregate Empirical Evidence

As far as the aggregate empirical studies are concerned, macroeconometric studies have tried to test the validity of the compensation mechanisms (see Section The Theory) within a partial or general equilibrium framework.

For instance, Sinclair (1981) put forward a macro- IS/LM scheme and concluded that a positive employment compensation can occur if the demand elasticity and the elasticity of factor substitution are sufficiently high. Using estimates based on US data, the author found a strong evidence supporting the mechanism 'via decrease in wages' but not the mechanisms 'via decrease in prices.'

Layard and Nickell (1985) derived a demand for labor in a quasigeneral equilibrium framework and stated that the crucial parameter was the elasticity of the demand for labor in response to a variation in the ratio between real wages and labor productivity; in fact, technical change increases labor productivity and – given an adequate elasticity – proportionally the demand for labor and this can be enough to fully compensate initial job losses. Using data for the UK economy, the authors estimated an elasticity coefficient equal to 0.9 and this was sufficient – in the authors' opinion – to rule out technical change from the possible causes of British unemployment. (See Vivarelli and Pianta (2000): Chap. 1, for an extensive critical discussion about the role of technology and the role of labor-market flexibility in determining employment performance.)

Using a similar approach, Nickell and Kong (1989) focused their attention to the operating of the compensation mechanism 'via decrease in prices' in nine UK two-digit industries. Putting forward a price equation where cost-saving effects of labor-saving technologies were fully transferred into decreasing prices, the authors found out that in seven sectors out of nine a sufficiently high demand elasticity was able to imply an overall positive impact of technical change on employment.

In Vivarelli (1995: Chaps 7–9) the direct labor-saving effect of process innovation, the different compensation mechanisms and the job-creating impact of product innovation have been tentatively represented and estimated through a simultaneous equations model over the period 1960–1988. Running three stages least squares regressions using Italian and US data, the author has shown that the more effective compensation mechanism is that 'via decrease in prices' in both countries, while other mechanisms reveal to be less important. In addition, the US economy has turned out to be more product-oriented (and so characterized by a positive relationship between technology and employment) than the Italian economy where different compensation mechanisms cannot counterbalance the labor-saving effect of prevailing process innovation.

Finally, Simonetti et al. (2000) have applied the same simultaneous equations macroeconomic model, running three stages least squares regressions using American, Italian, French, and Japanese data over the period 1965–1993. The authors have showed that the more effective compensation mechanisms were that 'via decrease in prices' and that 'via increase in incomes' (especially in European countries till the mid-1980s). The other mechanisms revealed to be less significant and conditional on the institutional structures of the different countries; for instance the 'mechanism via decrease in wages' turned out to be relevant in the American flexible labor market. Finally, product innovation significantly revealed its labor-intensive potentiality only in

the technological leader country in the period, namely the US.

Sectoral Empirical Evidence

The sectoral dimension is particularly important in investigating the overall employment impact of innovation; in particular, the compensation mechanism 'via new product' (which in recent times often takes the form of a compensation 'via new services') may accelerate the secular shift from manufacturing to services (see Evangelista and Perani, 1998; Evangelista and Savona, 1998).

On the other hand, in manufacturing new technologies seems to be characterized mainly by labor-saving ETC, only partially compensated by the market mechanisms discussed in Section The Theory.

For instance, Clark (1983, 1987) put forward a supply oriented vintage model investigating UK manufacturing. The author found out that the *expansionary effect* of innovative investments (Keynesian multiplier) had been dominant until the mid-1960s, when the *rationalizing effect* (due to labor-saving ETC incorporated in investments and scrapping) started to overcome the expansionary one.

More recently, Pianta et al. (1996), found out an overall positive relationship between growth in value added and growth in employment; nevertheless, especially in European countries, an important group of sectors appeared characterized by a marked labor-saving trajectory (restructuring sectors), with growth in production and a fall in employment.

In another study based on Italian data, Vivarelli et al. (1996) showed that in Italian manufacturing the relationship between productivity growth and employment appeared to be negative and, in particular, that product and process innovation had opposite effects on the demand for labor, in line with whatever has been discussed in the previous sections.

As already mentioned, the scenario may change if services sectors are taken into account: for instance – using standardized sectoral data derived from national CISs – Pianta (2000) and Antonucci and Pianta (2002) found an overall negative impact of innovation on employment in manufacturing industries across five European countries, while – in contrast – Evangelista (2000) and Evangelista and Savona (2002) found a positive employment effect of technological change in the most innovative and knowledge-intensive service sectors. (While a negative one in the case of financial-related sectors and most traditional services like trade and transport.)

Taking manufacturing and services jointly into account (using CIS cross-sectional sectoral data on relevant innovations for different European countries), Bogliacino and Pianta (2010) found a positive employment impact of product innovation (which turns out particularly obvious in the high-tech manufacturing sectors, see Mastrostefano and Pianta, 2009). Finally, Bogliacino and Vivarelli (2012) – running systemic generalized method of moments (GMM-SYS) panel estimations covering 25 manufacturing and service sectors for 15 European countries over the period 1996–2005 – found that R&D expenditures – mainly fostering product innovation – do show a job-creating effect. (As in the previous study, the labor-friendly impact of R&D expenditures turns out to be particularly significant in the high-tech sectors.)

Microeconomic Empirical Evidence

While the macroeconomic studies about the relationship between technology and employment seem to be confined to the 1980s and1990s, the literature devoted to the microeconometric investigation of the issue has begun later, but it is nowadays flourishing.

Starting from the earlier contributions, Entorf and Pohlmeier (1990) found a positive employment impact of product innovation – measured with a dummy – in a cross section of 2276 West German firms in 1984. The positive employment impact of product innovation in West German manufacturing was confirmed by Smolny (1998) using a panel of 2405 firms for the period 1980–1992.

Using the 1984 British Workplace Industrial Relations Survey, both Machin and Wadhwani (1991) and Blanchflower et al. (1991) found out a negative raw correlation between ICT adoption and employment; however, once controlled for workplace characteristics and fixed effects, the same correlation turned out to be positive.

In contrast with the previous studies, Brouwer et al. (1993) – using a cross-section of 859 Dutch manufacturing firms – discovered an aggregate negative relationship between aggregate R&D expenditures and employment (while the opposite emerged when only product innovation was considered). By the same token, Zimmermann (1991) – using microdata from 16 German industries – concluded that technological change was one of the determinants of the employment decrease in Germany during the 1980s.

Although the employment impact of innovation is not the main object of Doms et al. (1997), the authors found that advanced manufacturing technologies – measured by a set of dummy variables – have implied higher employment growth in U.S. manufacturing plants over the period 1987–1991.

More controversial results came from Klette and Førre (1998). The authors' database comprised 4333 Norwegian manufacturing plants over the period 1982–1992; in contrast with most of the other studies, they did not find any clear-cut positive relationship between net job creation and the R&D intensity of the examined plants.

Most recent studies fully took the advantage of new available longitudinal datasets and applied more sophisticated panel data econometric methodologies.

For example, Van Reenen (1997) matched the London Stock Exchange database of manufacturing firms with the SPRU innovation database and obtained a panel of 598 firms over the period 1976–1982. Running GMM-DIF estimates, the author found a positive employment impact of innovation and this result turned out to be robust after controlling for fixed effects, dynamics, and endogeneity.

By the same token, Blanchflower and Burgess (1998) confirmed a positive link between innovation (roughly measured with a dummy) and employment using two different panels of British and Australian establishments; their results showed to be robust after controlling for sectoral fixed effects, size of firm, and union density.

An interesting panel analysis was conducted by Greenan and Guellec (2000), using microdata from 15 186 French manufacturing firms over the 1986–1990 period. According to this study, innovating firms – defined according to the outcomes of an innovation survey – create more jobs than noninnovating ones, but the reverse is true at the sectoral level, where the overall effect is negative and only product innovation is job-creating. Interestingly enough, the opposite employment impact of innovation at the firm and sectoral level may be due to the 'business stealing effect' discussed above.

However, even when taking the business stealing effect into account (that is, controlling for lagged firms' employment and current sales). Piva and Vivarelli (2004, 2005) found evidence in favor of a positive effect of innovation on employment at the firm level. In particular – applying a GMM-SYS methodology to a longitudinal dataset of 575 Italian manufacturing firms over the period 1992–1997 – the authors provided evidence of a significant, although small in magnitude, positive link between firm's gross innovative investment and employment.

Using firm level data (obtained from the third wave of the Community Innovation Survey, CIS) from four European countries (Germany, France, UK, Spain), Harrison et al. (2008) put forward a testable model – based on Peters (2004) – able to distinguish the relative employment impact of process and product innovation (discrete variables). The authors concluded that process innovation tends to displace employment, while product innovation is basically labor-friendly. However, compensation mechanisms (see Section Introduction) are at work and in the service sectors are particularly effective through the increase in the demand for the new products. Hall et al. (2008) applied a similar model to a panel of Italian manufacturing firms over the period 1995–2003 and found a positive employment contribution of product innovation and no evidence of employment displacement due to process innovation.

More recently, Lachenmaier and Rottmann (2011) put forward a dynamic employment equation including wages, gross value added, years, and industries controls and alternative proxies (dummies) of current and lagged product and process innovation. Their GMM-SYS estimates – based on a very comprehensive dataset of German manufacturing firms over the period 1982–2002 – show a significantly positive impact of different innovation measures on employment. Partially in contrast with previous contributions, the authors found out a higher positive impact of process rather than product innovation. (However, this result can be due to the discrete nature of the adopted measure of process and product innovation (dummy variables). Interestingly enough, once the authors restrict their attention to (important) product innovation which went along with patent applications, they found out a highly positive and significant employment effect.)

Previous literature has very rarely split the empirical analysis according to sectoral belonging. One of the exceptions is the contribution by Greenhalgh et al. (2001), developing fixed effects estimates based on a panel of UK firms over the period 1987–1994. Consistently with most of the other studies here discussed, the authors found out a positive – albeit modest – effect of R&D expenditures on employment. However, once analyzed the data according to firms' sectoral belonging, the positive impact of R&D on employment turned out to be limited to the sole high-tech sectors.

In contrast – once split the sectors into high-tech and nonhigh-tech ones – Lachenmaier and Rottmann (2011) did not find any significant sectoral heterogeneity in the effects that innovation has on employment.

In a very recent study, Coad and Rao (2011) limited their focus on US high-tech manufacturing industries over the period 1963–2002 and investigated the impact of a composite innovativeness index (comprising information on both R&D and patents) on employment. The main outcome of their quantile regressions is that innovation and employment are positively linked and that innovation has a stronger impact for those firms that reveal the fastest employment growth.

Finally, Bogliacino et al. (2011, 2012) – using a longitudinal database covering 677 European manufacturing and service firms over the period 1990–2008 – found that a positive and significant employment impact of R&D expenditures is detectable in services and high-tech manufacturing but not in the more traditional manufacturing sectors.

On the whole – although previous microeconometric evidence is not fully conclusive about the possible employment impact of innovation – most of recent panel investigations tend to support a positive link, especially when R&D and/or product innovation are adopted as proxies of technological change and when high-tech sectors are focused on.

Conclusions

Preliminary conclusions have been already discussed within the previous sections; here it will be sufficient to briefly summarize the main findings of this study.

- Process innovation tend to be labor-saving, while product innovation exhibit a labor-friendly nature.
- According to the classical 'compensation theory,' market forces should assure a complete compensation of the initial labor-saving impact of process innovations; however, in Section The Theory different possible hindrances to the various compensation mechanisms have been critically discussed, reaching the general conclusion that compensation may be only partial, depending on the particular institutional setting and on the specific values of crucial parameters such as demand elasticity, degree of competition, capital-labor substitution, demand expectations, and so on.
- Since economic theory does not have a clear-cut answer about the employment effect of innovation, there is a strong need for aggregate, sectoral and microeconomic empirical analyses able to take into account the different forms of technological change, their direct effects on labor, the various compensation mechanisms, and the possible hindrances to these mechanisms.
- In particular, microeconometric studies have the great advantage to allow a direct and precise firm's level mapping of innovation variables, both in terms of inputs and outputs. Indeed, only firm's level data can account for R&D

expenditures, capital formation, product and process innovation, and directly relate them to firm's employment trends.

- In general, the microeconometric literature and particularly the most recent panel data analyses, tend to support a positive link between technology and employment, especially when R&D and/or product innovation are adopted as proxies of technological change and when high-tech sectors are focused on.

Abstract

We review empirical findings on the determination of R&D and R&D performance, as well as key questions that remain unaddressed. This article briefly considers the Schumpeterian hypotheses relating innovation to market structure and firm size, and considers in more depth the role of firm characteristics and industry-level variables – broadly characterized as reflecting demand, technological opportunity, and demand conditions – in affecting firms' innovative activity and performance.

Introduction

The writings of Joseph Schumpeter in the first half of the century pushed economists to appreciate the fundamental role of technological progress in affecting economic growth and social welfare. Since that time, economists have increasingly appreciated the economic significance of technological progress, and it is now common to hear that a firm's, an industry's, or even a nation's capacity to progress technologically underpins its long-run economic performance. Stimulated by Schumpeter's writings and Solow's (1957) subsequent 'discovery' of the contribution of technological change to economic growth, economists have conducted numerous empirical studies on the determination of innovative activity and performance. In this article we review the empirical literature and highlight the questions addressed and progress in the field.

The section 'Empirical Studies in the Schumpeterian Tradition' briefly reviews the 'neo-Schumpeterian' literature that examines the effects of firm size and market concentration upon innovation. The section 'Firm Characteristics' discusses the literature that considers the effect on innovation of firm characteristics other than size. The section 'Industry Characteristics' covers the literature on the three classes of factors affecting interindustry variation in innovative activity and performance: demand, appropriability, and technological opportunity conditions. We conclude in the section 'Conclusion.'

Empirical Studies in the Schumpeterian Tradition

This section briefly considers studies on the relationship between market concentration or firm size and innovative effort elicited by Schumpeter's controversial claims about the key role of large, monopolistic firms in advancing technology. (For a comprehensive review of this voluminous literature, see Cohen (2010).)

While Schumpeter (1942) confounded his discussions of the impacts on innovation of firm size and concentration, Galbraith (1952) explicitly argued that large firm size confers an advantage in innovation. A literal reading of Schumpeter's (1942) classic discussion suggests, however, that he was primarily impressed by the qualitative differences between the innovative activities of small, entrepreneurial enterprises and those of large, modern corporations with formal R&D laboratories. Nonetheless, the empirical literature has interpreted Schumpeter's claim for a large firm advantage in innovation as a proposition that innovative activity increases more than proportionately than firm size. With some exceptions (e.g., Scherer, 1965; Nelson et al., 1967; Pavitt et al., 1987) the Schumpeterian hypothesis about firm size has been tested by regressing some measure of innovative activity (input or output) on a measure of size. A thorough review of this literature (Cohen, 2010) highlights one longstanding, robust finding: a monotonic relationship between firm size and R&D. There is reason to believe that the source of this relationship is the R&D cost-spreading incentive effects of firm size (Cohen and Klepper, 1996). This cost-spreading effect of size itself, however, reflects underlying appropriability conditions that confine firms to exploiting their innovations in their own output, typically limited growth due to innovation, and market segmentation.

Schumpeter also argued that the possession of *ex ante* market power, linked to an *ex ante* oligopolistic (or monopolistic) market structure, also favored innovation. The profession's investigation of a relationship between market structure and R&D remains, however, problematic. Notwithstanding Schumpeter's arguments, no clear theoretical rationale for the relationship has emerged. And empirical results remain weak, with measures of market structure – albeit poor ones – explaining little of the variance in R&D spending. More importantly, the consensus of the empirical literature is that, to the extent that there is a relationship between market structure and R&D activity, it likely reflects the influence of other more fundamental determinants of technical advance, specifically technological opportunity and appropriability conditions, as well as the degree of market segmentation, all discussed below.

Firm Characteristics

This section considers firm-level determinants of innovative effort and performance other than firm size. Applied economists often control for firm size in their studies of innovative effort by using R&D intensity as the dependent variable measuring innovative effort. Employing the FTC Line of Business Program data that distinguish between the firm and its constituent business units, Scott (1984) found that once

 http://dx.doi.org/10.1016/B978-0-08-097086-8.71047-6

one controls for size by expressing R&D intensity as R&D normalized by business unit sales, fixed firm effects explain about 50% of the variance in R&D intensity. Economists have made, however, only modest headway in explaining interfirm differences in R&D intensity and performance since Cohen and Levin (1989) observed that the most widely considered measures of firm characteristics up to that time, namely cash flow and the degree of diversification, jointly explained less than 10% of the variance in business unit R&D intensity explained by fixed firm effects.

One firm-specific variable long considered as a possible determinant of R&D is cash flow, which may be the most thoroughly examined firm characteristic in this literature. Indeed, the claim that cash flow affects R&D constitutes one of Schumpeter's (1942) arguments for an advantage to large firm size. The rationale for considering cash flow as a determinant of R&D effort typically assumes that (1) capital markets are imperfect; (2) those imperfections especially constrain investments whose outcomes are more uncertain; and (3) the returns to R&D, as a class of investment expenditure, are more uncertain than the returns to, say, investment in property, plant, and equipment. The possibility that R&D expenditure is liquidity constrained due to capital market imperfections is important for policy makers because it represents another rationale for public support for R&D beyond the widely recognized market failure affecting R&D investment associated with R&D spillovers.

Many, but not all, of the studies have found that a firm's cash flow is associated with higher levels of R&D intensity or unnormalized R&D effort. Scholars have disagreed over the interpretation of this finding. Some have argued that it is difficult to distinguish cash flow as a measure of liquidity from its possible function as a signal of the future profitability of R&D investment. Indeed, the likelihood that R&D and cash flow both respond to the same demand shocks is likely the most challenging of the empirical issues facing researchers on this topic. Others question whether cash flow encourages R&D or whether it simply reflects the profitability of past R&D expenditures, which tend to be stable over time. Moreover, a positive relationship between cash flow and R&D expenditures may simply reflect their codetermination by a firm's underlying capabilities. Nonetheless, while the methodological challenges that plague this literature are not entirely addressed, the weight of findings suggests that cash flow likely contributes to R&D spending (Hall, 2002).

Another widely studied corporate attribute is diversification. The influence of product diversification upon basic research spending was first suggested by Nelson (1959), who argues that, because the results of basic research tend to be unpredictable, the diversified firm possesses more opportunities for exploiting the new knowledge. This argument implicitly assumes what Arrow (1962) expressed clearly: the market for information is imperfect and appropriability may be best achieved by the internal application of knowledge. The empirical results regarding the role of diversification have, however, been mixed (e.g., Link and Long, 1981). The absence of robust findings concerning an effect of diversification on R&D is unsurprising given the problems that beset this research. For example, it is just as likely, if not more, that the direction of the relationship runs opposite to that posited in the early work (Montgomery, 1994). Perhaps the most revealing work on the relationship between R&D and diversification has focused on the relationship between innovative performance and firm diversification across submarkets within one industry, namely drugs. Henderson and Cockburn (1996) observed a significant, robust positive relationship between the number of research programs pursued by drug firms (where a program is distinguished by therapeutic area), and the productivity of each program's R&D, measured by the number of 'important' patents produced, suggesting the presence of scope economies where diverse R&D activities are related across submarkets.

Differences in R&D activities and innovative performance across firms have focused some economists' attention on the influence on R&D of differences in firms' R&D-related capabilities. Before discussing this literature, it is important, however, to take heed of Scott's (1991) point that one should not presume that heterogeneity in firms' R&D activities or performance necessarily signal differences in capabilities rather than differences in the incentives faced by comparably capable firms. Indeed, in Cohen and Klepper's (1996) R&D cost-spreading model, firms of different sizes may pursue different types of R&D not because of differences in capabilities, but due to the different R&D incentives conditioned by size. Obviously, however, differences in capabilities may contribute to differences in the level and direction of R&D effort.

This modest economics literature on the role of firm-specific capabilities in affecting innovation raises the question of exactly what kinds of capabilities matter for innovative activity and performance. The research broadly distinguishes two sorts. Clark, Henderson, Mansfield, Mowery, Nelson, and others emphasize the role of organizational or procedural capabilities in conditioning the R&D productivity of firms. In this view, firms may pursue similar innovative activities, but some firms are more successful than others in either generating or profiting from innovation due to superior organization of internal processes. In contrast, Jewkes et al. (1958), Cohen and Klepper (1992a, b), and others focus on differences in firms' areas of substantive technological or domain expertise which affect the success of their pursuit of different innovative activities.

The firm characteristic that economists have been long believed to affect R&D performance is the link between R&D and other functions within the firm. Starting with the work of Mansfield (1968), economists such as Teece (1986) and Mowery and Rosenberg (1989) have highlighted the importance of the links across marketing, manufacturing, and R&D in conditioning innovative success. Exploring complementarities between R&D and other functions within the firm or across different activities within the R&D function itself poses, however, a challenge for both methods and measurement (cf Arora, 1996). The issue is how can one estimate such complementarities given the possibility that an apparent complementarity across activities or capabilities may rather reflect the effect of unobserved firm heterogeneity; that, for example, there is some unobserved firm characteristic that is driving what is believed to be complementary activities as well as R&D performance itself.

With notable exceptions (e.g., Cockburn and Henderson, 1998; Henderson and Cockburn, 1994), economists have been slow to take up the call to consider the role of capabilities within the R&D function itself. Although one could treat such

capabilities as observable, the construction of measures of R&D-related capabilities suitable for analyzing innovation in large samples spanning multiple industries is a formidable challenge. Construction of such measures demands detailed knowledge of the nature of the technologies and other activities associated with innovation in each sample industry. Moreover, it is not even clear how such capabilities would be defined or distinguished in a broad cross section. Partly reflecting these difficulties and reflecting economists' inattention to organizational processes and the nature of organizations more generally, only modest progress has been made in conceptualizing differences in firm R&D-related capabilities in ways that yield testable, interpretable hypotheses.

A small number of empirical studies on the role of capabilities in determining innovative performance within industries date from the late 1980s and early 1990s. Clark et al. (1987), for example, identify wide disparities in firms' R&D productivities in the international automobile manufacturing industry. This study offers evidence that these disparities result from differences in the organization of product development in these firms, including the degree to which tasks are subdivided, how the different phases of the development process are coordinated, how technical problems get solved, the relative autonomy of the project leader, and the nature of the links between product development and upstream applied research.

Notwithstanding the type of capability that is thought to matter, many studies of firm capabilities assume that key R&D-related capabilities are exogenously given. This literature, however, does not make a strong theoretical case for this assumption, nor does it, with the exception of the limited evidence offered by Henderson (1993), indicate whether or under what circumstances it may be true. Although partly a question of time horizon, case study, and anecdotal evidence support to some degree the assumption that selected R&D-related capabilities are exogenous by highlighting the fact that a firms' 'core' capabilities are hard to change. The question of whether R&D capabilities are endogenous or not suggests the utility of entertaining the fundamental questions raised by Clark (Clark et al., 1987: 781) about why such differences exist, how they evolve, and why they persist.

Related to the observation that firms differ in their innovative activities and capabilities is the notion that no one firm may pursue all the activities necessary to generate and commercialize a given innovation. This observation should push economists to understand that technical advance within an industry is commonly realized through the interactions of firms that are distinguished by size, expertise, and other attributes, and thus one might consider that technical advance is not promoted by some ideal firm type – distinguished by any particular single or set of characteristics – but by the interactions of firms with differing and complementary features, no less by the interactions between firms and other institutions such as universities. Accordingly, it would be important to understand the range and distribution of attributes that might promote technical advance, as well as factors that promote the efficiency of firms' interactions with one another and with other institutions that support technical advance.

Industry Characteristics

In seeking to understand why industries differ in the degree to which they engage in innovative activity, empirical researchers such as Pakes and Schankerman (1984) have come to classify explanatory variables under three headings: product market demand, technological opportunity, and appropriability conditions. The subsections that follow summarize and interpret what is known about how demand, technological opportunity, and appropriability conditions vary across industries and how they contribute to an explanation of interindustry differences in innovative activity.

Demand

In his seminal work on technological change in various capital goods industries, Schmookler (1962, 1966) made two arguments. The first, general claim was that the direction and rate of technological change could be explained as the outcome of the behavior of purposive, profit-seeking firms, and was thus amenable to economic analysis. To demonstrate the importance of economic incentives in general, he highlighted the role of demand in particular. To substantiate that demand determined the rate and direction of inventive activity, he marshaled evidence indicating that cyclical changes in the output of capital goods and in capital expenditures by downstream industries 'led' cycles in the time series of relevant capital goods patents.

Schmookler's focus on the role of demand sparked a lively debate among economic historians and other economists concerning whether 'demand-pull' or 'technology-push' was the primary force behind technological change. Schmookler's proposition that demand almost alone determines the rate and direction of technical change has not, however, survived empirical scrutiny. The consensus, after dozens of case studies, is that the Marshallian scissors cuts with two blades. Perhaps the most persuasive refutation of Schmookler's proposition is offered by Parker (1972) and Rosenberg (1974), who document several important historical examples (e.g., the mechanization of hand operations in agriculture, the use of coal as an industrial fuel) in which the sequence of particular applications of a 'generic' technological idea was determined not by demand, but by the state of knowledge and inherent technological complexity of particular industrial applications. Offering statistical evidence that both blades matter, Stoneman (1979) showed that the cost of, as well as the demand for inventions conditioned the level of innovative effort. Scherer (1982) offered additional evidence, finding that dummy variables classifying industries by technology (chemical, electrical, mechanical, etc.) and variables representing demand conditions were statistically significant in a regression analysis of line of business patenting activity, but the technology variables explained considerably more variance.

There are two principal respects in which interindustry differences in demand conditions might be expected to affect the incentives to engage in innovative activity. First, as Schmookler himself emphasized, there is the size of the market, which might be represented in static terms by a scale parameter and in dynamic terms by a rate of growth. The argument is straightforward. The (expected) investment required to yield

a given reduction in unit cost or a given improvement in product quality is independent of the level of output that will be produced once the innovation is made. The benefits realized by such investment, however, are proportional to the size of the market in which the innovation is used. More inventive activity would therefore be expected in the larger of two markets, holding constant the cost of innovation; in two markets of equal size, more inventive activity would be expected in the market that is expected to grow more rapidly.

Second, Kamien and Schwartz (1970) suggested that the price elasticity of demand will also affect the marginal returns to investment in R&D. They demonstrated that the gains from reducing the cost of production (process innovation) are larger the more elastic is demand. On the other hand, Spence (1975) demonstrates that the gains from improvement in product quality (product innovation) will, under many circumstances, be larger the more inelastic is demand, since inelastic demand tends to magnify the gains from a rightward shift in the demand curve. Thus, the effect of price elasticity will be ambiguous in empirical studies that do not distinguish between process and product innovation.

The distinction between process and product innovation raises the subtle conceptual and operational question of how to characterize the demand conditions relevant to product innovation. In the case of intermediate products, such as those studied by Schmookler, the demand function for inputs of higher quality can in principle be derived from estimates of final product demand and the downstream production technology. It is more difficult to characterize and estimate the demand for consumer product innovation. A variety of econometric techniques can be used to estimate the demand for routine improvements in some measurable dimension of product quality (e.g., hedonic price models, Lancasterian demand models, and discrete choice models). Such techniques, though useful in particular applications, are unlikely to be fruitful in cross-industry analysis, since they require very detailed data and special modeling efforts for each specific product.

In regression studies of R&D investment, demand conditions, although rarely featured, have often been considered. A variety of categorical variables have been used, presumably as proxies for interindustry differences in price elasticity. Most common are those distinguishing durables from nondurables, as well as those distinguishing consumer goods from material inputs or investment goods. Some researchers have used input–output data on the disposition of industry output (i.e., the shares of output destined for personal consumption, intermediate use, exports, the government sector, etc.). Although these categorical and input–output variables are sometimes statistically significant in regressions explaining a measure of innovative activity, there are no notably robust findings.

To capture market size and growth effects, sales and the rate of growth of sales are typically used, despite the obvious problem that these variables do not measure demand conditions, but the interaction of demand and supply. Moreover, since improved products will have larger markets, sales revenue and growth are endogenous with respect to innovation. Measures of market size that are defensibly exogenous and stand apart from supply conditions have just recently been incorporated into a study of innovation and R&D, though only for the pharmaceutical industry, by Acemoglu and Linn (2004). With a dependent variable being the number of new drug approvals by the US FDA in broad categories distinguished by therapeutic effects, the exogenous component of potential market size is derived from Current Population Survey data on demographic trends combined with differences in the population age profiles of expenditures and use for different types of drugs.

Sutton (1998) highlights submarket homogeneity as another dimension of demand that conditions R&D spending. In his model, submarket heterogeneity, and the interaction between the nature of products and the buyer preferences that give rise to it, condition the degree to which firm size (or, more properly, business unit size) offers an R&D cost-spreading advantage, and, thus, the degree to which firm size increases the incentive to conduct R&D. One might argue that submarket heterogeneity simply begs the question of how one defines a market, though, as discussed at length by Sutton, market definitions need to be empirically implementable.

A limitation of economists' consideration of demand is the assumption, highlighted by Malerba (2007), that buyers are passive participants in the innovation process. This is far from true. von Hippel, 1988 shows, for example, that in semiconductors and scientific instruments, some customers – what he calls 'lead users' – may not only suggest ideas, but may themselves act on them, modifying firms' products, and, in von Hippel's view, anticipate or even shape the future direction of product innovation. Economists would surely benefit from a more detailed institutional understanding of the role of buyers in affecting the rate and direction of technical advance.

Technological Opportunity

Much of the empirical literature takes for granted that technical advance, at prevailing input prices, is 'easier' (less costly) in some industries than in others. Although it is widely accepted that industries differ in the opportunities they face for technical advance, there is no consensus on how to make the concept of technological opportunity precise and empirically operational. In the framework of the standard neo-classical theory of production, technological opportunity can be regarded as the set of production possibilities for translating research resources into new techniques of production that employ conventional inputs. Some theoretical treatments have thus represented technological opportunity as one or more parameters in a production function relating research resources to increments in the stock of knowledge, with the stock of knowledge entering as an argument, along with conventional inputs, in the production function for output (e.g., Griliches, 1979). Related approaches treat technological opportunity as the elasticity of unit cost or unit price–cost margin with respect to R&D spending (Dasgupta and Stiglitz, 1980; Spence, 1984; Sutton, 1998), or as a shift parameter determining the location of an innovation possibility frontier representing the trade-offs in the direction of technical change (Levin, 1978).

Rosenberg (1974) suggested a simple mechanism by which the growth in scientific knowledge encourages innovation; he

claimed that "as scientific knowledge grows, the cost of successfully undertaking any given, science-based invention declines …" (p. 107). Conceptualizing R&D as a stochastic search process, Evenson and Kislev (1976) and Nelson (1982) similarly suggested that 'strong' science affects the cost of innovation by increasing the productivity of applied research. Nelson in particular argued that a strong science base narrows the set of research options and focuses attention on the most productive approaches. The consequence is that the research process is more efficient. There is less trial and error; fewer approaches need to be evaluated and pursued to achieve a given technological end. From this perspective, the contribution of science is that it provides a powerful heuristic guiding the search process associated with technological change. Evenson and Kislev (1976) and Nelson (1982) enrich this characterization of the role of science by suggesting that stronger science may also provide a larger pool of candidate approaches to achieving some technological objective, thereby increasing the expected payoff, although at the cost of broadening the search. Cohen and Klepper (1992b) suggest that a more vital underlying science and technology may also increase the number of technological objectives to be pursued rather than simply increase the number of approaches to pursuing any given objective.

Most attempts to represent technological opportunity as a determinant of innovative activity in regression studies have followed the practice introduced by Scherer (1965), who classified industries on the basis of the scientific or technological field with which each was most closely associated. Scherer's initial classificatory scheme (chemical, electrical, mechanical) was refined in his subsequent work (1967, 1982), and variants have been used by numerous investigators. Although Scherer intended to capture interindustry differences in the vigor of advance of underlying scientific and technological knowledge, he recognized that statistical results obtained with the use of such crudely defined categorical variables would also likely reflect the influence of unspecified industry practices or demand effects not captured by other regressors. Nonetheless, the simple classification of industries into a small number of technology groups has powerful statistical consequences; it has explained a substantial fraction of variance in patenting activity (Scherer, 1965, 1982) and R&D intensity (Scott, 1984).

Using the survey data described in Levin et al. (1987), Klevorick et al. (1995) examine across a broad range of manufacturing industries the general relevance of 11 fields of basic and applied science to each industry's technological progress, as well as the relevance of university-based research for those same fields. Klevorick et al. find that the reported overall relevance of science to technical advance varies considerably across industries and identify the industries to which science appears to be most relevant. For science in general, they found drugs and semiconductors closest to a field of science among the industries for which they received 10 or more responses. While these survey results represent an important first step in examining an important dimension of technological opportunity, empirical economists need to build on these initial efforts and develop data – survey and other data – that are more readily interpretable and speak more directly to some of our theoretical notions of the role of science in promoting technical advance.

Linked to the progress of underlying science and technology that may affect an industry's technological opportunity is the contribution of technical knowledge from sources external to the industry: suppliers, customers, universities, technical societies, government, and independent inventors. A voluminous institutional literature documents the contribution of such extraindustry sources to technological progress. The case studies of Jewkes et al. (1958) contain instances of virtually every type of external influence. A notable example of institutional–empirical work on this subject is von Hippel's (1988) treatment of the contributions of users to technological development in a variety of industries, including scientific instruments and semiconductor process equipment. Klevorick et al. (1995) offer the first broad, cross-industry empirical examination of the contributions to technical advance made by extraindustry sources of embodied and disembodied knowledge. Not surprisingly, they found that what they call sources 'within the industrial chain,' such as buyers and materials and equipment suppliers, contribute more to most industries' technical advance than nonindustrial sources such as universities and government labs.

A key source of technological opportunities that reflects the influence that innovation in one industry may have on downstream and complementary technologies are 'general purpose technologies' – a term coined by Bresnahan and Trajtenberg (1995) to characterize technologies that may enable and stimulate applications across a range of markets (possessed of what they call, 'generality of purpose'), and whose prospective applications typically elicit follow-on R&D, thus exhibiting 'innovational complementarities.' In other words, there are technologies that, once developed, provide significant, and often pervasive technological opportunities for innovation in other industries.

An extensively studied extraindustry influence on technological opportunity is that of government. In numerous sectors, such as agriculture, aircraft, electronics, and medicine, government has contributed to reducing the cost of innovation and has influenced the direction of industrial research by its own research, as well as by both subsidizing and sponsoring private sector research and disseminating technological knowledge developed in its own labs and elsewhere. The distribution of government expenditures on R&D across industries is highly skewed, especially in the United States, where industries supplying the military, and, more recently, universities conducting research in the life sciences, are the principal recipients of R&D support. Although its direct role in creating and disseminating knowledge is substantial in some sectors, its indirect influence is also felt through a variety of other channels that have different impacts across industries. Most important is the impact of government demand on the rate and direction of innovation.

Over the past 30 years, scholars have also studied intensively the effect of university research on industrial innovation. Nelson (1986) and Klevorick et al. (1995), for example, find university research to be an important source of innovation in only selected industries, including especially those associated

with biology. In contrast, also relying upon survey data, but collected over a decade later, Cohen et al. (2002b) found the impact of public research (including university and government sources) to be more pervasive. Using state-level patent, innovation, and patent citation data, respectively, Jaffe (1989b), Acs et al. (1992), and Jaffe et al. (1993) also show that the effects of university research on innovation increase with geographic proximity.

Just as spillovers from extraindustry sources may augment a recipient firm's technological opportunity; so may spillovers within an industry reduce the own R&D required to achieve a given level of technical performance. There have been several econometric attempts to measure the effects of both extra-industry and intra-industry spillovers on firms' productivity, including efforts by Jaffe (1986, 1988, 1989a) using data on the distribution of patents by patent class to measure the technological relatedness of every pair of firms in a sample of over 500 firms. For each firm, he constructed a 'spillover pool,' defined as the sum of all other firms' R&D weighted by the measure of relatedness. Bernstein and Nadiri (1988, 1989) took a more direct approach to estimating the magnitude of spillover effects by including the R&D capital of other firms or industries in the cost function of the receiving firm or industry. They found evidence of large efficiency gains from both intra-industry and extraindustry spillovers. On the basis of these and other studies, Griliches (1992), in a review of the econometric literature on R&D spillovers, concluded that, "R&D spillovers are present, their magnitude may be quite large, and social rates of return remain significantly above private rates" (p. 24).

Thus, most of the work on technological opportunity over the past decade has focused on particular sources – notably that emerging from public research and other firms. With the exception of Klevorick et al. (1995), there is a paucity of work that probes the nature and sources of technological opportunity more generally, or that operationalizes the concept and examines its role across industries, despite the fact that a number of prominent scholars consider technological opportunity to be not only a key determinant of R&D and technical advance, but foundational to the evolution of market structure and entry, as well as key to the links across market structure, entry, and innovation (e.g., Geroski, 1994; Sutton, 1998).

Appropriability

To the extent that new knowledge is transmitted at a relatively low cost from its creator to prospective competitors, and particularly to the extent that such knowledge is embodied in new processes and products that may be copied or imitated at relatively low cost, appropriable rewards may be insufficient to justify innovative effort. In theory, patents solve the problem of imperfect appropriability; the exclusive right granted by society enhances the incentive to invent by sanctioning restriction of an invention's use. To the would-be inventor, the prospect of a patent represents the expectation of ex-postmarket power that Schumpeter claimed was an essential spur to innovation. In fact, however, industries differ widely in the extent to which patents are effective. The evidence suggests that patents are featured as a means of protecting innovation in only a few industries, while, in most industries, firms tend to rely more heavily upon other means of appropriation. In some instances, imitation is costly despite the absence of strong patent protection. In others, investment in complementary capabilities such as marketing and manufacturing can facilitate appropriation when neither strong patents nor technical barriers to imitation are present. Reflecting the Levin et al. (1987) and Cohen et al. (2000) survey results, the consensus is that patents are limited in their effectiveness in most manufacturing industries because patents rarely prevent 'inventing around,' while disclosing information that facilitates such activity (Levin et al., 1987; Cohen et al., 2000).

The Levin et al. (1987) survey revealed that firms in many industries tend to regard mechanisms other than patents as quite effective in appropriating the returns from innovation. In numerous lines of business outside the chemical and pharmaceutical industries, firms reported that the advantages of a head start and the ability to move quickly down the learning curve were more effective means of appropriation than patents. In their survey administered 11 years later in 1994, Cohen et al. (2000) also found that firms typically believed means other than patents to be most effective in protecting innovation. But, in contrast to the Levin et al. results, secrecy was ranked as the most effective mechanism in 17 of 34 three-digit SIC code level manufacturing industries, and thus at least comparable in importance to lead time, which is ranked first in 13 industries.

In addition to differences in appropriability conditions over time and across firms of different sizes, appropriability conditions may also differ across regions. Although Arundel (2001) found appropriability conditions in Europe to resemble that of the United States, Cohen et al. (2002a), found sharp differences between the United States and Japan, where the effectiveness of patents in protecting product innovations were at least comparable to the other major mechanisms, and equivalent to the most effective mechanism, lead time.

Despite the evidence on interindustry – no less cross-national – differences in appropriability conditions, there is, however, no clear empirical consensus about whether greater appropriability encourages innovative activity. The simplest hypothesis, derived from the standard argument supporting the patent system, is that innovative activity will increase monotonically with appropriability because spillovers create a disincentive to innovative effort. In the model of Cohen and Levinthal (1989) the simple 'disincentive effect' of spillovers remains, but there is an offsetting incentive to invest in 'absorptive capacity'-building R&D to make use of them, suggesting that R&D spillovers are not as much of a public good as previously supposed. Levin and Reiss (1988) similarly suggested another countervailing incentive effect. To the extent that own and rival R&D are different but complementary, the knowledge produced by a firm's competitor may raise the marginal product of own R&D. Thus, the same knowledge flows that can diminish appropriability can increase the productivity of other firms' R&D and offer a positive incentive to invest in R&D. In either instance, an increase in spillovers (decrease in appropriability) has an ambiguous effect on industry R&D. If we broadly consider the Levin and Reiss and Cohen and Levinthal models as together positing a complementarity effect of R&D spillovers, then a key question for

understanding R&D incentives and innovation at the industry level is what factors condition the trade-off between spillovers' negative appropriability incentive effect versus their positive complementarity effects. Empirical findings to date do not establish whether the net effect of appropriability on R&D incentives is positive or negative, nor do we yet know the extent to which the net effect varies across industries, no less what may condition different effects observed across industries.

Rather than focusing on appropriability conditions generally, economists over the past 25 years or so have focused on the narrower and directly policy-relevant question of the effects on R&D and innovation of patents in particular. Economists have argued that the impact of patents – and stronger patents – on innovation is not as straightforward as popularly believed. There are theoretical reasons to question whether patents stimulate R&D. For example, although the expectation of monopoly rents should induce inventive effort, the prospect of patent disclosures can offset the private gains from patenting (cf Horstmann et al., 1985). Also, 'stronger' patents mean that, not only any given firm's patents, but also those of its rivals are stronger (cf Jaffe, 2000), possibly dissuading rival innovation. Merges and Nelson (1990) and Scotchmer (1991) argue that, where technologies progress cumulatively and patents are broad, the licensing or enforcement decisions of upstream inventors may retard downstream innovation. Heller and Eisenberg (1998) and Shapiro (2000) also argue that, in some instances, the fragmentation or proliferation across different stakeholders of potentially overlapping patent rights for a given technology can raise transaction costs sufficiently to retard or even block otherwise worthwhile innovation.

A key question given our concern with the drivers of innovative activity is the effect of patents on R&D. The antecedent question, however, is whether the patenting of inventions indeed yields a return, presumably by increasing the value of whatever inventions that are patented. The work of Pakes, Schankerman, Lanjouw, and colleagues, in their examinations of European firms' patent renewal decisions (e.g., Schankerman, 1998; Schankerman and Pakes, 1986; Lanjouw, 1998), suggest, for Europe, that patent protection does yield a return, sometimes substantial, with estimates of the implied subsidy to R&D varying between 10% (Lanjouw, 1998) to as much as 25% (Schankerman, 1998). Using the Carnegie Mellon Survey data for the US manufacturing sector, Arora et al. (2008) estimate the 'patent premium' – the proportional increment to the value of an invention conferred by patenting it – by estimating a structural model linking a firm's R&D effort with its decision to patent, recognizing that R&D and patenting affect one another and are both driven by many of the same factors. Their results indicate that, even though most innovations are not worth patenting, patents are valuable for a subset of innovations and thus do provide incentives for R&D. Moreover, conditional on patenting, the expected premium is substantial, with firms earning an average 50% premium, with this conditional premium ranging from an average of 60% in the health-related industries to about 40% in electronics. Employing the estimated coefficients, the authors also simulate the effect of changing the premium on R&D. They find that an increase in the mean of the patent premium distribution for a typical manufacturing firm in their sample would significantly stimulate R&D, especially in industries where the patent premium is high, such as drugs, biotech, and medical instruments. Thus, consistent with the descriptive findings of Levin et al. (1987) and Cohen et al. (2000), Arora et al. (2008) find that patents are not as central to the protection of inventions as other mechanisms except in a few, selected industries; their estimates confirm that in most industries, patenting the *typical* innovation is indeed not profitable. However, even in these industries, some innovations are profitable to patent.

An important feature and limitation of both the patent renewal and Arora et al. (2008) studies is their focus on the direct, private returns to patenting. By restricting R&D spillovers or potentially creating complex thickets, patents may, however produce aggregate, more system-wide effects not easily discerned by considering the responses of individual firms to changes in the strength of their own patents. Indeed, empirical studies of the relationship between patenting and innovation at the aggregate levels of nations or industries have provided rather more ambiguous results about the impact of patents on innovation, although this ambiguity may be partly due to difficulties in controlling for the endogeneity of patent policy or the joint determination of R&D and patenting. Thus, neither the results of the patent renewal studies, nor those of Arora et al. (2008) imply that patents necessarily yield a net social welfare benefit overall.

The main lesson of the Levin et al. (1987) and Cohen et al. (2000) surveys is that firms use a range of appropriability mechanisms – and patents are not the central means of protection in most US manufacturing industries. Economists have not, however, devoted the energy to the empirical study of the use of the other mechanisms as they have to patents, nor, in their analyses of the effects of patents, have they explicitly considered patents as just one of several possible mechanisms in any given industry. Likely reasons for this inattention include the difficulty of finding suitable data and formulating precise tests to distinguish among competing hypotheses concerning the deployment of the different means of appropriation.

Conclusion

This article attempts to highlight important and robust empirical findings on the determination of R&D, and R&D performance, as well as key questions that remain to be addressed. We have divided our consideration across three broad areas of inquiry: (1) the Schumpeterian hypotheses relating innovation to market structure and firm size; (2) the role of firm characteristics; and (3) the role of industry-level variables broadly characterized as reflecting demand, technological opportunity, and demand conditions. The overall conclusion is that progress in advancing our empirical understanding of the determination of firms' and industries' innovative activity and performance has been uneven.

Despite the consensus regarding the importance of demand, appropriability, and technological opportunity conditions in affecting innovative activity and performance, consideration of the role of these variables has a considerable distance to go.

These three classes of industry-level variables appear to explain a good deal of the variance in firms' innovative activities. Yet, our understanding of how this influence is exercised is limited. We have ideas, some clearer than others, of how different dimensions of demand, technological opportunity, and appropriability may influence innovative activity and performance. Our tests for the presence and importance of these particular effects are, however, often indirect.

In comparison to our understanding of the influence of industry-level variables, our understanding of the role of firm-level variables is more primitive still. Economists began to consider the influence of firm characteristics from the mid-1980s through the mid-1990s, but there has been less work on the topic since. Although it is difficult to collect data on firm characteristics, empirical analysis is made all the more challenging due to the possible endogeneity of many of these characteristics.

Several overarching lessons may be drawn from the empirical literature on innovative activity and performance. First, we need more and better data on the range of variables considered. Better measurement of innovative activity itself is also essential. Consider, for example, the absence of measures of innovative activity that occurs outside of the formal labs and accounting categories encompassed by R&D, which Mansfield (1968) suggests may represent about 50% of manufacturing firms' investments in product and process innovation. In addition, we lack accurate measures of innovation itself – the output of innovative activity. Although progress has been made on measuring innovation with citation-weighted patent counts (Trajtenberg, 1989, 1990), it is understood that such a measure is still flawed given differences in the propensity to patent across industries and firms as well as our limited understanding of citing behavior (cf Alcacer et al., 2009). Finally, another major lacuna in our understanding of the determinants of innovative activity and performance is our ignorance of innovation in the service sector, except for a modest literature on financial services (Frame and White, 2004; Lerner, 2006). This gap is not simply a matter of a lack of data. It speaks to our very notion of innovation, and how to capture innovation when a good deal of it occurs outside of R&D labs, and especially in the context of client-specific relationships.

Perhaps one of the more basic lessons to emerge from the empirical literature is that, although testing loosely motivated hypotheses may yield empirical results, even robust ones, their interpretation can be challenging, and the insight that can be gleaned from such findings is often limited in the absence of underlying theory. However banal, the prescription that modeling can serve as a useful handmaiden to empirical analysis has often been overlooked in studies of innovation.

There is also, however, an important role to be played by more inductive efforts. Consider, for example, that much of our empirical understanding of innovation derives not from the estimation of econometric models, but from the use of other empirical methods. The historical and case study literatures provide a rich array of insights and factual information, and often constitute a source of hypotheses and inspiration for more rigorous approaches. More strikingly, many of the most credible empirical regularities have been established not by estimating and testing elaborate models with published data but by the painstaking collection of original data, often in the form of responses to simple questions. Even as econometric methods advance and the quality of published data improves, it will be important to remain catholic in the application of empirical techniques.

Acknowledgments

This article is a condensation of the author's 2010 review, *Fifty Years of Empirical Studies of Innovative Activity and Performance*, (Cohen, 2010) which updated and drew heavily from a prior survey written by the author (Cohen, 1995), which, in turn, drew extensively from a prior survey written by Richard Levin and the author (Cohen and Levin, 1989).

Abstract

In sociology, the idea of innovation was primarily introduced by Gabriel Tarde. Tarde's theory has been further developed by diffusion theorists. Entrepreneurship is part of behavioral innovation theory just as technological, social, and behavioral changes. Three different perspectives may be identified in the emerging reborn innovation theories around 2000: Entrepreneurship, technology-economic, and strategic. Innovation as a phenomenon and concept has recently been brought out of the market-economic academic sphere into the public sector and the civil society, conceptualized as social entrepreneurship and social innovation.

An innovation is a renewal of behavioral or material structures or practices. More formally, innovation can be defined as the introduction of a new social, material, or economic phenomenon or a new combination of old ones. Examples include the introduction of new technology, a new type of organization, or a new fad of young peoples' dating behavior. Innovation refers to both behavioral and technological changes. In sociology, the concept of innovation has been used to explain social change, indeed it was only later that it was used in economics to explain economic growth. Recent theoretical developments have again focused on the sociological side of innovation (e.g., Sundbo, 1998; Franz et al., 2012).

This article takes its point of departure in the assumption that innovation is fundamentally behavioral and thus a sociological phenomenon, even when its result may be technological or economic. Innovation is created by individuals and their will to change, however, their behavior is influenced by social and economic structures. This perspective is in line with Giddens' (1984) structuration theory that, put somewhat simplistically, argues that social structures provide the framework in which actors act and whom either uphold or change those structures. This article will discuss different aspects of innovation theory and has a theory-historical perspective, however, the emphasis will be on contemporary theory.

Innovation is about the process and the result, not the idea. An idea or an invention is necessary to create change, but it does not in itself create any change. Innovation as a concept has two meanings. One refers to the process of changing elements or structures, the other, the result of the process. The result may be a new type of behavior or, for example, a new good or service (such as the personal computer or Facebook). Even when the result is a new technology or good, the use of it requires social acceptance and willingness to change habits and attitudes. Even in economic theory, innovation is seen as a new product that is only sold on the market if people buy it. People must want to use it and they will perhaps need to adapt their behavior to be able to use it.

Classic Theory

In sociology, the idea of innovation was primarily introduced by Gabriel Tarde (1890, 1897). He developed a theory stating that societal changes are introduced by individuals who start behaving in a new way or use new tools. These individuals are imitated by others, who again are imitated by others. This is done via communication and social interaction that defuses the change more widely throughout society. Tarde saw this as a complex social process that included resistance to the new phenomena, social conflicts, and problems. The new behavior and the structures they result in are, perhaps, advantageous to some individuals and social groups, but disadvantageous to others.

Joseph Schumpeter is regarded as the father of innovation theory within economics. Schumpeter emphasized the behavioral aspects of innovation processes and he has thus contributed to behavioral theory as much as to economic theory. For the early Schumpeter, some individuals, whom he termed entrepreneurs, have a drive to create new activities and change the market and production systems and thereby create economic growth (Schumpeter, 1934); this theoretical position is often called Schumpeter I as he later changed his view and explained economic growth and social changes in terms of organized structures (Schumpeter, 1939) such as large firm organizations that decide to innovate to get a better competitive position on the market or political organizations that introduce new structures into society; this theoretical position is often called Schumpeter II. In addition, he discussed whether innovation leads to capitalism or socialism and how it influences democracy (Schumpeter, 1943).

Diffusion

Tarde's theory has been further developed by diffusion theorists, particularly Everett M. Rogers (1995) who stated that innovations diffuse through society following an S-shaped acceptance curve. In the earliest phase, a few people accept the innovation (early adopters), it then spreads as more people accept it and finally the least change oriented, the so-called laggards, will accept it. The S-curve theory of diffusion, similar to Tarde, makes an implicit assumption about social stratification. The first adopters are individuals who have a high social status, the last ones are people with low status. Rogers supported his arguments with the case of agricultural diffusion. Those that first accepted new technology were the

landed proprietors, then came the farmers, and last the smallholders. However, this pattern may not always occur. Some behavior and technology is adopted first by the lower status groups. Some entrepreneurship theories point to the opposite cause–effect relationship – that being the first to introduce a new innovation may give someone high status, at least in the long run.

Rogers also emphasized how social structures, for example, governmental regulation or culture, influence the diffusion processes. A common point of departure in an institution, for example, a university, can lead to development of a series of innovations in a local community, as was the case with the emergence of Silicon Valley in California. Following this line of thought the rapidly growing technology business area is a result of entrepreneurs not imitating each other, but using their competencies, social relations, and earlier innovations as the basis for developing new innovations. This can be seen as a diffusion of entrepreneurship within a local community.

Within anthropology, the diffusion of innovations has been a core factor in explaining cultural change in isolated and traditional cultures. New phenomena from outside a culture are, from time to time, adopted by this culture. In such cases, anthropologists talk about assimilation or acculturation of the new phenomena that can be behavioral or material. The central issues in anthropological theory are whether the phenomena will be adopted or rejected, how they are adopted, and what social consequences the adoption will have (cf Barnett, 1953). The new things may be introduced by a member of the community who has traveled abroad, seen something new, and brought it with him back home. The new things may also be introduced if immigrants have come to the community. Sometimes the new thing exists side by side with an old or several new phenomena compete to become dominant.

Entrepreneurship

Entrepreneurship is part of behavioral innovation theory. The entrepreneur is a person. The idea of entrepreneurs as creators of change stems from economics. As early as 1803, Jean-Baptiste Say formulated a law of economic development based on entrepreneurship, and Schumpeter continued this line of thinking. An individual entrepreneur introduces something new (a technology, a product, or a behavior) that penetrates the market and then changes the market conditions. This contrasts with the behavioral sciences where there is no clear idea about one person creating and carrying out the whole change process. In Tarde's theory, several people are involved in the change process. The diffusion of innovations is seen as a process having different stages where different individuals and social subsystems participate in the development of the innovation.

Schumpeter's and the economic theory's way of thinking about entrepreneurship is indeed connected to innovation – the entrepreneur is an innovator. However, in his early work, Schumpeter (1934) emphasized the entrepreneur's activity rather than the innovations (new elements) that were possible outcomes of the activity. The entrepreneur is a person who is extremely active in creating and organizing production and sales activities. These activities may be based on a new idea or invention, but that does not need to be the case. The entrepreneur can take others' ideas or inventions as the basis for his business activities. It is important that he creates activities that change the economic market's 'rules of the game.' The entrepreneur in economic theory refers to a person who creates new business activities, and there is an ongoing debate about whether the activities must contain something new, that is, an innovation, to be called entrepreneurship or not. In some languages, entrepreneurship just means small business.

In the behavioral sciences, such as sociology and anthropology, there has also been some focus on individuals as creators of innovation and social change, however, not as much as in economic theory. Rather innovation has been understood as a systemic phenomenon, or as one in which several individuals are involved (cf Tarde's and Rogers' adopters, imitators, and opponents). This may be a logical consequence of sociology's attempt to create theories of how the development of social systems can be explained by system factors and not by individuals, which was a general understanding before sociology emerged. However, more recently, there has been a fundamental discussion within sociology about whether individuals or the structures themselves determine social change, the so-called actor–structure debate referred to above (e.g., Giddens, 1984). Until recently, this debate had not been connected with the concepts of innovation or entrepreneurship.

Social Change

In the 1950s and 1960s, a theory of social change based on innovation and diffusion emerged in the United States (e.g., Zollschan and Hirsch, 1964). At the time functionalistic theory dominated American sociology and a part of the functionalistic approach was to see society as fundamentally stable. Sociology was inspired by economics and the natural sciences to see societies as systems in, or seeking, equilibrium. This did not mean that there are no differences or conflicts between people and groups; however, a social system was seen as developing by itself toward a state in which differences were institutionalized without open conflicts and social structures becoming permanent. When this state is reached, the social system functions best; every element, relation and structure, has its function in maintaining the optimal equilibrium situation.

Within functionalist sociology, there was an acknowledgment that social systems may change. However, this was seen as an exception and only happening rarely. Social change could therefore be a special discipline within sociology that deals with the special situations, where changes in a social system take place (e.g., Moore, 1967). These changes may be revolutionary such as when a social revolution or a war suddenly breaks out. This happens very rarely. Most changes, when they happen, are changes in parts of the system. Social change was a discipline aimed at explaining why these partial changes happen. Innovation and diffusion became core concepts in this explanation (LaPiere, 1965). The social change theories operate with new elements, may emerge within the equilibrium system, just as happens in, for example, biological equilibrium systems (e.g., fish gain new skin colors or generic mutation). 'Innovation' was introduced to explain why and how these new elements enter the system.

The theory argues that even social equilibrium systems may develop in some cycles or from time to time slowly developing toward a new equilibrium. Social change as a discipline studies these 'changes within the stable social system' by emphasizing innovations and the diffusion of them into and within the system. Innovation is a rare phenomenon. Social change theories were less occupied by explaining why innovations emerge – they more or less based that explanation on the Tardian theory of entrepreneurship and diffusion. It was held that innovation processes were started by individuals (entrepreneurs), who must be characterized as deviants; they have a mentality and behavior outside the norm. This 'deviant' behavior may in the long run be seen as positive by the members of the system, but in the first phase it is often seen as negative – just because it is deviant. The social change theorists were more occupied by discussing what the innovations and their diffusion do to the social system that led to different theories of 'system conformity' dynamics where the single innovations were seen as part of a pattern, not as anarchic changes that point in every direction.

Social change theories may be seen as more 'reformist' in their view on what innovation and entrepreneurship can do to the social system than Schumpeter was in his view on what innovation and entrepreneurship can do to the economic system. Schumpeter talks about swarms of innovations that completely destroy economic equilibrium ('creative destruction' as he called it), which is a radical view in contrast to the mainstream economic equilibrium theory.

Technological and Behavioral Changes

Originally, innovation theory dealt with both behavioral and material changes; and both the macro (society) and micro (organizational) levels and this also characterized the social change theories. Later in the mid-twentieth century, the interest in innovation become focused on the organizational level and on technological changes that are narrower, structured, and science- or engineer-based changes concerning the material aspects of life. The wider behavioral aspects became overshadowed by the focus on technological change and firms' position in the market competition. Innovation theory became an economics and business discipline.

This development due to the realization that World War II had resulted in the development of many new war technologies. After the war it was observed that these war technologies could be used in civil society and create economic growth and welfare. Science-based technological innovations were seen as a basis for the welfare society. Therefore economic innovation theory became a theory on technological innovation.

Technological innovation also became a topic in sociology. Theories on how technology is developed in society were put forward by, for example, Rosenberg (1976). An emerging discipline of science and technology in sociology attempted to explain how research and technology development activities could be understood and explained. In sociology, technological innovation and change was, however, mostly discussed in relationship to behavioral changes. A core theme was whether technological changes create social changes or vice versa. Ogburn (1957) put forward a theory of cultural lag which suggested that technological changes determined by technological innovations come first and change the material structures of society while the necessary cultural changes to utilize the new technologies lag behind and only come after some time.

Ogburn's theory may be interpreted as a kind of technological determinism where technological innovation determines social change. Later, a criticism of technological determinism emerged. In that discussion, some sociological theorists stated that social structures and processes determine the changes, even the material ones. It might be the case that technological innovations are necessary to develop society, but it is social needs and aims that select which technologies are introduced and diffused through society. This position was among others taken by the Science and Technology Studies (STS) approach (e.g., Bijker et al., 1987). This led to a development of theories that by some theorists were accused of expressing a behavioral determinism, where the materiality and science and technological innovation do not have any power to determine behavior or change society. More modified positions such as the actor network theories (ANT, e.g., Latour and Woolgar, 1979) emerged. They started to include material (or technological) innovations as determinants of social change in addition to social innovations.

The interest in innovation in the behavioral sciences decreased after the 1960s (except within the above mentioned technology-social structure determination fight, which did not primarily focus on the concept of innovation). Innovation became a topic dealt with in economics and was synonymous with technological innovation. In economics, the focus was much more on the invention, not the diffusion of innovations. Economic theory and analyses emphasized research and development of technology at macro (societal) and micro (firm) levels mostly concerning large companies. Entrepreneurship was by and large forgotten.

Contemporary Theory

The reappearance of the concept of innovation in behavioral theories started in the late 1980s, and innovation theory has increasingly become an important part of mainstream theories. More recently, innovation theories in economics have broadened their scope thus they are now concerned with entrepreneurship in addition to technological innovation and research and development in large organizations.

Three Perspectives

Around 2000, the reappearance of innovation theory pointed in several directions mixing elements from old and new theories. Political and business interests in society led to a new focus on how innovation could create economic growth and thus increase welfare and provide advantages in market competition. A wish to increase the number of innovations led to an interest in understanding how innovations emerge and how the development of innovations could be influenced. The interest and theorizing has concerned the macro, societal, and micro, organizational levels.

Three different perspectives may be identified in the emerging reborn innovation theories (Sundbo, 1998). They

offer different explanations of innovation and appoint innovation to different agents. The perspectives are summarized in the following model (Figure 1):

One of the perspectives, entrepreneurship, is a revival of the old entrepreneurship-based innovation theories, but it is now more focused on the emergence of entrepreneurs than on diffusion of innovations. Most of the theoretical discussions are related to the economic perspective: how do business entrepreneurs emerge and what are the social and economic conditions for them remaining entrepreneurs and business to grow?

The technology-economic perspective is a continuation of the interest in economic theory for technological innovation, research, and the economic results of technological innovation. However, this interest has been extended into other behavioral sciences such as sociology. In addition to the STS and ANT traditions, a focus on the organizational conditions for development of technological innovations and for their diffusion in the society has developed.

The third, strategic, perspective is new in behavioral and economic theories. It is a more sociological or anthropological perspective. It is focused on understanding the social processes that lead to innovations. Innovation is a goal-oriented and planned activity; it has led to the suggestion of using the notion strategy to characterize this perspective. Innovation is seen as an activity carried out in a social system determined by structural factors as well as actors. The goal, not the invention or idea, is in focus. The goal is one for a total group or social system such as a firm, a social group, or even a society. Ideas and inventions flow around in the social system, however they are selected and some of them are supported. Somebody takes the decision about which ideas to promote. This may be the result of more or less democratic or inclusive processes, but some individuals need to take the final decision or take the responsibility for carrying out the collective decision and reflect on the result of the strategy; if the result is not as desired, other innovations may be introduced (Sundbo and Fuglsang, 2002). The individuals who make the decisions are in contemporary social systems normally managers (which is a wide concept including, e.g., ministers, enterprise owners, and informal leaders of social groups). Even if the goal setting may be a collective process, the managers have a great influence on the innovation processes and the direction of social change. The manager is the main agent of innovation and change.

The three perspectives are metatheoretical ideal types and are often mixed in innovation theories and empirical research. The following presents contemporary innovation theories.

Entrepreneurship Roles and Networks

Entrepreneurship has increasingly been narrowed to entrepreneurial activities that lead to some kind of innovation (e.g., Casson, 2013). The theoretical interest has changed focus from not only looking at how entrepreneurs emerge, but also how they develop innovations. One discussion is whether entrepreneurs are driven by an internal force and the will to establish projects or firms, or whether they are driven by opportunities, for example, in the market.

Another discussion concerns how entrepreneurs act in their attempt to develop and implement the innovation and, maybe, as a consequence, enable their firm (or other organizations) to grow. They often use social networks, and entrepreneurship is increasingly seen as a social activity where the entrepreneur has or establishes relations to other people who again have relations to other people and the entrepreneur thus has access to many people in, often loosely coupled, networks. The networks are both professional – which can give access to knowledge, capital, labor force, and so forth – and social. If there are no positive mutual social attitudes, the networks will rarely work professionally either. Theories even state that innovation can happen in networks where several entrepreneurs collaborate or where one cannot point to any individual being the entrepreneur more than others. Entrepreneurship can be collective and several entrepreneurs can collaborate and engage in group innovation.

Entrepreneurship thus is increasingly seen as a collective activity that may be conditioned by social structures and not only by an individual drive that may stem from the person's

Figure 1 Three perspectives on innovation. Based on Sundbo, J., 1998. The Theory of Innovation. Edward Elgar, Cheltenham. p. 159.

adolescence. A theoretical development, inspired by social psychology, has been to see entrepreneurship as roles in innovation processes. Different roles have been identified, examples include the analyst who contributes knowledge, the actor who makes things happen, the sponsor or business angel who support the innovation, the community entrepreneur who supports networking, the extrapreneur who from within an organization propagates for entrepreneurship in other organizations.

Technology-Economic Innovation: Knowledge Diffusion

In recent research and theory, the interest for technological innovation has changed from a focus on the research and development processes to the diffusion of formal knowledge, typically scientific knowledge, which is the basis for technological innovation. The knowledge bases have increased dramatically as many new universities have been established and old ones have grown. Private knowledge bases have emerged within knowledge services (e.g., via new consultancy and private laboratory industries) and IT Networks such as the Internet extend access to knowledge bases dramatically. Firms do not need to have internal research to get new technology; they can procure that from outside and then internally develop it to create innovations. Knowledge has been seen as the most valuable economic factor (above labor and capital) because it is the basis for innovation, which economically has become the most important factor because it creates economic growth. Schumpeter's theory about organized innovation (Schumpeter II) has become mainstream within economic and welfare policy and in economic theory.

Knowledge diffusion has become a core topic within the technology-economic perspective (e.g., Nonaka and Takeuchi, 1995). The importance of knowledge institutions at a macro level and knowledge management at the micro (organizational) level has become the subject for innovation theories. Themes have concerned, among others, how some knowledge is formal and how some is tacit – informal knowledge that people have internalized, for example, in their work activities. Theories speculate on how formal knowledge can be utilized to create innovation, how tacit knowledge can be converted into formal knowledge, and how firm organizations can store knowledge about innovation processes – called organizational learning. Theories also speculate on how organizations can absorb external knowledge. One specific theory deals with absorptive capacity (Cohen and Levinthal, 1990), which is organizations' ability to process external knowledge and use it for innovation. The absorptive capacity is assumed to be highest if managers and employees have a higher education thus they seek formal external sources (such as research results, consultancy knowledge, and so forth) and are able to transform it into innovations.

Strategic Reflexivity and Innovation in Organizations: Open Systems

The strategic perspective focuses on how innovations are developed in organizational processes (e.g., Mintzberg, 1989; Sundbo, 2001). The development of innovation moves in several directions. One is a top-down process, where the top management of the organization (normally thought of as a firm organization) decides that the firm should develop thus innovation is necessary. The management therefore induces innovation processes in the organization by setting up formal innovation project groups and gives incentives to people in the organization, people outside the project groups also contribute to the innovation processes. Many employees thus have a role in innovation processes. Employees can also be internal entrepreneurs or intrapreneurs (cf Pinchot, 1985), and innovation processes can start from bottom-up. Employees can be entrepreneurs for a period, sometimes often, sometimes once in their lifetime.

Innovation thus becomes a complex process where many actors are active and they play together with, or against, the organizational system. Innovation may even create conflicts because it may lead to organizational changes that can change the power basis of different departments and individuals. Innovation is within this theoretical perspective seen as a broad phenomenon. It can include the development of new technology or new social behavior such as new organizational or management forms or a new market or communication behavior. This complex system must be managed and the task of that belongs to the top management. This is complicated because many ideas for innovation are presented and the most important is whether the environments (in business, the market; in politics, the voters) will accept the innovation. The managers often use a formulated organization policy, strategy, or business plan as the guide for making decisions. However, they need to reflect on how the innovations work in the environments, which may be called strategic reflexivity (Sundbo and Fuglsang, 2002). Employees are often involved in the strategic reflexive process because they encounter the environments (customers and clients) and therefore observe how the innovations work.

Innovating organizations are, in this perspective, considered as open systems (cf Chesbrough, 2006). They interact with the environments to reflect on the introduced innovations and to get new ideas for innovation. The strategic aim is to satisfy the environments (e.g., the market or a political system). Theory and research has therefore been interested in how users of the potential innovations can be involved in the innovation process (e.g., Sundbo and Toivonen, 2011). Firms imitate innovative behavior that has been developed in or by civil society. Some authors, such as Eric von Hippel (2005), claim that this will democratize the innovation processes in society.

Social Innovation

Innovation as a phenomenon and concept has recently been brought out of the market-economic academic sphere. There has, for example, been an increased political focus on innovation in the public sector. The strategic innovation theory perspective has been applied to public organizations, primarily with the aim of studying how innovation can make the public sector more efficient and simultaneously create more user satisfaction, for example, that citizens are more satisfied with public services (e.g., Windrum and Koch, 2008).

This interest has also spilled over to discussions about developments in civil society and the role innovation and

entrepreneurship play. Research suggests that social problems are often solved by innovations outside the formal public sector and are carried out by individuals, who may be characterized as entrepreneurs, and by groups and local networks. A question for future theory development is therefore whether the formal political system will be unable to solve the challenges of an aging population, increased bureaucracy, lifestyle determined health problems, and so forth. The solutions may come from civil society that might be more oriented toward innovation activities. A concept of social entrepreneurship has been developed to explain these activities (e.g., Ziegler, 2011). The entrepreneurship theory has been extended to cover the whole of society to include other sectors of civil society than the social sector, for example, cultural activities, sports activities, and so forth. The theoretical understanding focuses on networks and local communities.

Social entrepreneurship creates innovative solutions to societal problems. The development of the theoretical understanding of innovation is reverting back toward the social change theories of the 1950s and 1960s; however, it has dropped the functionalistic approach of that tradition. The concept of social innovation is increasingly used to characterize and understand innovation processes outside the technological-economic sphere. However, social innovation is not a very clear concept. It is used to characterize innovations within the social sector of civil society (a kind of voluntary social policy effort), but also nontechnological innovations in general and innovations initiated by employees, managers, users, and others outside the professional research and technology sphere (Cajaiba-Santana, 2014).

The Future of Innovation Theories

Innovation theory is facing a challenge to its foundation as a result of the recent developments relating to, for example, discussions concerning strategic and social innovation tendencies in the society. Innovation was introduced as a concept to understand change that was seen as an exception to stability and equilibrium. But, if the society is constantly moving and everything is changing, which many observers claim, change is not an exception rather it is the norm. Has the concept of innovation become meaningless? One may create theories about how changes are happening within particular field and their direction, but does a general theory of innovation have any meaning? Furthermore, it is postulated that all individuals need to adapt to changes and to be active in that process (e.g., if they want to make career and not loose their job). If everybody must carry out some kind of role with respect to change, we may ask whether or not the concept of entrepreneurship is meaningful?

The answer to these theoretical challenges is not yet clear. The answer might be that the concept of innovation will be restricted to technological business renewals – the technology-economic perspective. It might be the case that innovation theory develops into a new fundamental discipline, in line with psychology or sociology, that has the aim of explaining that every system has a driving force to change (maybe not only social systems, but also material systems and individuals) – a general change theory. It might also be that theory will state that people by nature both want change, but also stability and the task is to understand how much change, or innovation, is wanted or optimal in different social systems. It might also be that innovation theory will discuss socio-psychological issues by defining different roles in change process. Whatever, the extension of the use of the innovation concept calls for a, maybe radical, revision of innovation theory reflecting on what the theory fundamentally tries to explain.

Abstract

The concept of 'instinct' has served as an influential way to conceptualize the recurrent forms, the ultimate motivations, and the possible heritability of human behaviors. Theories of instinct had a strong influence on nineteenth century psychology and social science. By the 1920s, however, instinct theories were the target of considerable criticism, which questioned whether it represented a single, scientifically valid, and observable phenomenon and whether it was relevant to the explanation of complex human behavior. The notion fell out of favor in the social and behavioral sciences by the 1930s, despite sporadic attempts to defend and rehabilitate it.

The concept of 'instinct' has served as an influential way to conceptualize the recurrent forms, the ultimate motivations, and the possible heritability of human behaviors. In the social and behavioral sciences, this notion has been strongly debated, with authors variously arguing that it refers to mental impulses or to physiological reflexes; that it represents the ultimate source of human behavior or is largely irrelevant to its explanation; that it denotes definite responses or amorphous tendencies; that it is fundamentally fixed or malleable; and that, as an explanation, it is scientifically sound or tainted with metaphysics.

The reputation of instinct as an explanatory concept rose strongly as Darwinian evolutionary principles were adopted by the social and behavioral sciences. Theories of instinct had a strong influence on late nineteenth and early twentieth century psychology and social science, but the notion was also the target of heavy criticism and fell out of favor as an explanation of human behavior by the 1930s. As alternative conceptual schemes for the explanation of human motives and conduct have developed in these sciences, attempts to rehabilitate or reformulate the notion of instinct have been largely overshadowed. In general, the modern human sciences have sought to explain the regularities of human behavior by more proximate psychological and environmental causes and to place emphasis on the social or cultural conditioning of behavioral patterns, at the expense of theories of instinct.

The Evolution and Heritability of Behavior

No systematic attempt is made here to trace the popular, philosophical, or theological uses of the term 'instinct.' However, there were several identifiable precursors to the modern biological conceptions of instinct in the eighteenth and nineteenth centuries that were drawn upon by later authors in the social and behavioral sciences. A notion akin to instinct in explaining the behavior of living organisms goes back at least as far as Aristotle, whose *De Anima* argued that the actions of animals are directed by an impulse in accord with the requirements of their natures. Other classical philosophical warrants include René Descartes' epistemological doctrine of 'innate ideas,' denoting those mental states or faculties necessary to explain the basic features of the mind that are apparently not the result of experience, and the political philosophy of 'natural law,' which led Thomas Hobbes and many other authors to ground human rights in often conflicting doctrines of man's innate qualities or needs.

In the popular writings on 'natural history' prior to the spread of modern evolutionary theories, instinct was commonly referred to as a special impulse imparted to a species by an act of divine creation. Each species was therefore thought to have an endowed set of fixed dispositions as part of its particular mode of existence, and humans were thought to be endowed not with instincts, but with reason, to guide their actions. In English-language scholarship, William Paley's (1802) *Natural Theology* was particularly influential in defining instinct as 'a propensity prior to experience and independent of instruction,' and in arguing that such complex, innate behavioral tendencies are evidence of the existence of a divine creator. Other major natural philosophers of the eighteenth century, including Goethe and Buffon, expressed similar views.

The works of Georges Cuvier (1769–1832) and Jean-Baptiste Lamarck (1744–1829) are representative of two of the major scientific directions in understanding instinct prior to the Darwinian revolution and their work served as critical reference points for later theories. Cuvier's (1817) *The Animal Kingdom* formalized the popular conception of instinct, arguing that they are innate, species-particular, 'involuntary mental impulses' that guide the conduct of 'lower' animals. They do not manifest any visible marks in the physiology of the organism, he thought, and they are not subject to fundamental change across generations. The prevalence of instinct in a species varies inversely with its level of intelligence and, consequently, instinct occupies a nearly irrelevant place in explaining human conduct. Cuvier illustrated the fundamental place of 'fixed instinct' in explaining the behavior of lower animals with now-classic examples including the stereotyped formation of honeycomb by bees and nests by birds; and he was an early proponent of the concept of 'social instincts' to explain the behavior of communal species.

In contrast to Cuvier, Lamarck's *Zoological Philosophy* (1809) argued that instincts are subject to change in the course of an individual organism's life. In this view, instincts may be acquired over the course of an organism's experience as 'habits,' these habits can affect the physiological structure of the organism and these 'acquired characteristics' may then be

directly heritable. This early evolutionary theory, he thought, allowed him to better explain the demonstrable fact that apparently innate behavior patterns can be changed in a permanent and heritable way, as in the 'domestication' of animals. The theory seemed to offer an explanation of how complex mental states are reproduced or spread in subsequent generations of a species, but the supposed 'inheritance of acquired characteristics' was controversial from its first printing and later proved incompatible with the biological mechanisms of inheritance elaborated by Darwin and others.

In his foundational *On the Origin of Species* (1859), Charles Darwin (1809–82) admitted that explaining instinct by means of 'natural selection' was one of his theory's most serious challenges and he consequently addressed the topic in detail. He referred to instincts as actions "performed in the same way by many individuals of a species, without experience and without their knowing the purpose." The role of instincts is comparatively less important in 'higher' than in 'lower' animals, he argued, and in man there are few if any fixed instincts. Although Darwin left open the possibility that some instincts may be inherited as Lamarckian 'acquired habits,' he argued that in most cases they could clearly be explained by principles of natural selection. Crucial to his argument, he sought to demonstrate that there are spontaneous variations in instincts manifested by individuals of a species just as there are variations of physical traits, and that these variations may affect the survivability of organisms that exhibit them in the ways predicted by natural selection processes. Darwin examined possible objections to this theory in depth, including apparent cases of inheritance of new habits by the offspring of domesticated animals; the development of instincts that seem too intricate to have developed spontaneously; instincts that appear to go against self-preservation; and others. In each case, he found that the observations could be explained by natural selection or human-directed selective breeding of instinctive tendencies that are already naturally exhibited.

Although he did not address all the possible problems, Darwin outlined the first coherent evolutionary theory to account for both the heritability and variability of complex behaviors. Other evolutionary theorists, especially Alfred Russel Wallace (1823–1913) and August Weismann (1834–1914), sought to eliminate all vestiges of the Lamarckian 'acquired habits' view of instincts that remained in scientific and popular discussions of the topic, including among those heavily influenced by Darwin such as Ernst Haeckel, Herbert Spencer, and Wilhelm Wundt. For Wallace (1875) and Weismann (1889), instincts may, in many cases, be perfected in the course of experience (by the exercise of imitation, memory, or observation) but they are rooted in heritable physiological structures. The modifications that an organism undergoes in life do not directly pass to later generations. Instead, spontaneous genetic variations in organic structure predispose some individual organisms to develop more adaptive behavioral tendencies and those more adaptive 'predispositions of the germ,' as Weismann termed them, are more likely to be inherited. Indeed, Weismann's theory of the 'germ plasm' as the mechanism for inheritance is key to the so-called 'modern evolutionary synthesis.'

Wallace further proposed that the notion of instinct should be used only where it can be conclusively demonstrated that no instruction or observation is necessary for the performance of some complex act. On the basis of this criterion, he argued that most of what was attributed to instinct, including classic examples such as bird nesting, can actually be shown to be dependent on a combination of learning, simple physiological reflexes, and the structure of the local environment. Wallace, along with Haeckel (1834–1919), T.H. Huxley (1825–95), Lewis H. Morgan (1818–81), and others, criticized instinct as a scientific explanatory device, because of its ambiguous and multiple definitions and because it seemed to rely on a 'metaphysical' notion of motive 'impulse,' rather than on observable faculties to explain behavior. As a supposed 'first cause' of behavior, it seemed to stifle inquiry into the nature and causes of instincts, themselves. J. Mark Baldwin (1861–1934), C. Lloyd Morgan (1852–1936), and others, considering the growing number of experimental studies on animal instinct, argued that their authors should make a principled distinction between biological evolution passed through the germ plasm, and 'social heredity,' in which behaviors are passed directly from one individual to another by imitation, instruction, or shared experience. This social heredity, too, could be shown to be functional for the survival of a species, and could help explain the immense, variable array of human behavior patterns.

Instinct in Human Psychology

Prior to Darwin's (1871) own detailed application of his evolutionary principles to humans in *The Descent of Man*, Herbert Spencer (1820–1903), Francis Galton (1822–1911), and others had already commented extensively on this topic. Galton's studies of 'hereditary genius,' for example, purported to demonstrate that human intellectual and moral traits are subject to the same laws of inheritance as physical traits, which helped explain the appearance of families of purportedly 'natural' leaders and savants. Spencer too argued for the inheritance of 'psychical' as well as physical characteristics in his pre-Darwinian (1855) *Principles of Psychology*, which laid the groundwork for one of the most influential understandings of instinct in human psychology. Considered physiologically, instincts are 'compound reflex actions,' according to Spencer, and are formed in the same way as habits: over the course of experience the frequent co-occurrence of certain simple reflexes leads to their coordination, such that complex actions tend to unfold more automatically with repetition. In this way, he developed a coherent physical theory that linked simple neuromuscular reflexes with complex instinctive behaviors and provided an account of instincts that did not rely on teleological mental faculties, such as will or consciousness. Indeed, he argued that intelligence, itself, developed by the further coordination of complex nerve pathways and was therefore a consequence of, rather than in opposition to, instinct. In animals with higher intelligence, the modes of behavior are not stereotyped wholes but rather separable bundles of reflexes that could be recombined in ways that allowed for intelligent adaptability to variable surroundings. This 'chained reflex' understanding of instincts was further developed by biologists Jacques Loeb (1859–1924), H.E. Ziegler (1858–1925), and others and became central to later Behaviorist criticisms of the utility of the instinct concept.

Authors considered the founders of modern human psychology, especially William James (1842–1910) and Wilhelm Wundt (1832–1920), built critically upon the work of Spencer and Darwin regarding instinct. James (1890) viewed instincts as the 'functional correlates' of an organism's 'structure.' In this view, instincts are 'impulses' that naturally but implicitly tend toward expression but which do not have only one fixed goal or form of release. Yet he also favored Spencer's physiological interpretation, which classed instincts with reflexes instead of by means of the purposes they appear to serve to the observer. James' theory consequently sought to combine the seemingly opposed 'mental impulse' and 'physiological reflex' views into a single 'functional' statement.

If, in James' view, each separate impulse is also a coordinated reflex, then there must be an immense number of so-called 'instincts' to account for all the adjustments that complex organisms make to stimuli in their environments. And indeed, contrary to Darwin and Cuvier, James proposed that humans have a greater variety and number of instincts than any other animal, a point on which Spencer and Wundt agreed. These numerous impulses often come into conflict with one another in conduct, leading humans to a life of "hesitation and choice," an "intellectual life," not because they have fewer instincts but because they have so many that they inhibit the expression of one another. James proposed one of the earliest lists of definite human instincts (following William Preyer and G.H. Schneider in this regard), which included actions that definitely require learning (e.g., walking) alongside apparent simple reflexes (e.g., suckling or biting). James' eclectic list emphasized the native diversity of impulses in human action. Additionally, James' and Spencer's emphasis on the inability to physiologically distinguish instinct from habit, in effect, divorced the psychology of behavior from a definite evolutionary mechanism. While James favored the 'natural selection' view of Darwin, other leading psychologists, including Wundt and Theodule-Armand Ribot (1839–1916), drew the opposite conclusion. The phenomena of instinct, they argued, are consistent with a notion of inheritance by 'acquired habits.'

Wundt (1894) further emphasized the inadequacy of a purely mechanical view of human instinct, stemming from Spencer. Like James, he preferred the notion of 'impulse' or 'drive' (German: *Trieb*) to 'instinct' in human psychology; and more than James he emphasized the ways in which the expression of impulse was regulated by its orientation to goals and its association with affective states. Such impulses are, thus, centrally important motive forces in Wundt's 'voluntaristic' psychology. Other psychologists of the late nineteenth and early twentieth centuries, including C. Lloyd Morgan, L.T. Hobhouse (1864–1929), and G.T. Ladd (1842–1921), also elaborated what some called the 'appetitive' nature of instincts. In this view, instincts are not merely the sum of a chain of reflexes but are also a particular state of the organism that persists through the action, and without which the reflexes would not be discharged by appropriate stimuli or combined effectively.

A similar view was also espoused by prominent 'vitalist' philosophers of this period, including Hans Driesch (1867–1941) and, to a certain extent, Henri Bergson (1859–1941). Driesch (1908), in particular, insisted on the specificity of instincts in contrast to simple reflexes and habits. Instincts are peculiar in that, although they may in some cases be improved through repetition, they are complete from their first expression. In addition to being composed of chained reflexes, instincts are impelled toward a more-or-less definite end condition (e.g., a finished spider web) and their course persists even in the face of obstacles that require additional effort or adjustment of operations. For Driesch, these findings provided some of the strongest evidence for the existence of a 'vital principle' at work in the organism that could not be explained on purely mechanical principles. Much of this psychological literature on instinct as a motive force drew upon a broader tradition regarding the irrational sources of human behavior. Driesch, for example, drew inspiration from Schopenhauer, Nietzsche, Eduard von Hartmann, and others. However, in the subsequent history of the human sciences, the most influential and controversial author on these questions has been Sigmund Freud (1856–1939).

Most current understandings of Freud's 'drive theory' do not equate it with a 'biological instinct' theory. This confusion persists in English, however, because influential translations of Freud's work have used the word 'instinct' to translate his notion of 'drive' (*Trieb*). Drives, in Freud's theory, are not prefixed in form or object. Instead, he sought to explain the intricate and problematic processes involved in dynamically structuring these energies, including the formation of repressions and sublimations and the sequences of attachments to external- and self-objects. Freud modified his theory of drives several times, most notably in *Beyond the Pleasure Principle* (1922), where he proposed that in addition to the 'libido' there is also a fundamental 'death instinct' or 'death drive,' that is necessary to explain the persistent enactment of unpleasurable experiences. Most schools of psychoanalysis that have been influential in the social sciences, especially ego-psychology, social psychiatry, self-psychology, and post-structural psychoanalysis, for all their disagreements, share an emphasis on the necessity of structuring the otherwise indeterminate drives, and hence, a largely 'non-instinct' view of Freud's theory of drives.

Kurt Koffka (1886–1941) also proposed a *Gestalt* theory of instincts, which drew upon existing 'appetitive' theories but sought to avoid their 'vitalistic' or 'mentalistic' implications. In Koffka's (1924) view, instincts are continuous courses of movement oriented to an end as well as regulated by a stimulus, and in this way they form 'articulate wholes.' Instincts, unlike mere reflexes, actively seek stimulation and that stimulation is given not primarily from the external environment but from the tensions or needs of the organism itself. Koffka attempted to elaborate a theory that could account for the forward impulse of instincts without implying a guiding will or consciousness, by arguing that they constitute 'open' or 'transitional' situations in the dynamic equilibrium of the organism that continue to operate until they reach an end-state of 'closure,' perhaps prefiguring a more cybernetic or systems-theory view of instincts. After the initial positive reception this theory had little further influence, at least in part, because of the growing body of criticisms of the instinct theory in the 1920s.

Instinct in the Social Sciences

In the social sciences of the late nineteenth century, influential early followers of Darwin placed emphasis on the role of

instinct in explaining the origins of complex human institutions and behaviors. Galton's (1883) observations of herd animals and human crowds led him to claim that humans possess a fundamental 'gregarious' or 'social' instinct that is at the origin of social behaviors. This gregarious instinct, he proposed, had evolved to ensure mutual security in social groups, but in exchange for this stability it tended to retard cultural innovation and progress. Galton argued that these instincts may not be perfect guides to action in modern society and could actually be dysfunctional, pointing to what he saw as the general servility of the vast majority of people. In his view, human instincts were adapted to a precivilizational state and had not had time to adapt to the conditions of industrialization. Galton's conclusions were closely tied to his advocacy of eugenics and he argued that measures should be taken to ensure that the individuals most adapted to advanced civilization, reproduce for the betterment of human progress.

Spencer and others took a somewhat more charitable view in proposing that human instincts, because they are subject to the same laws of evolution as other traits, could be shown to vary in determinate ways across races and historical epochs, according to the dominant conditions to which the human groups had to adapt. Other authors, including Pyotr Kropotkin (1842–1921), Henry Drummond (1851–97), and John Fiske (1842–1901), even argued that social instincts represent a separate evolutionary 'factor,' which shifts selection pressures to the level of the social group rather than the individual organism and are, therefore, productive of continued social development. Spencer, of course, also proposed that human society was analogous to a natural organism, and he went so far as to suggest that something analogous to 'self-preservative instincts' are present, not only in individuals who make up social institutions, but in those institutions themselves. Indeed, in his *Principles of Biology* (1864), Spencer coined the term "survival of the fittest" to describe the working of natural selection, and he made clear in his *Principles of Sociology* (1898) that he considered this a principle that operated at the social as well as the individual level.

Virtually all of these 'Social Darwinist' authors sought to show that human morality could be attributed to the influence of social instincts. In his *The Descent of Man*, Darwin (1871) posited that, although the particular features of morality are learned, the seed of morality is found in the instincts that lead humans to take pleasure in association, to feel sympathy with others, and to provide services for one another. In human conduct there are situations, Darwin argued, in which one instinctive tendency temporarily dominates others; yet memory allows instincts that go unsatisfied to return to the individual's awareness, and the outstanding human capacity for language allows unsatisfied impulses to be expressed and judged communally. Over the course of experience, humans develop self-command to prevent over-expression of self-preservative instincts at the expense of others, and in this way moral conscience arises. Further, Darwin argued that if the source of moral behavior is the 'social instincts,' then behavior need not be explained by means of hedonistic or utilitarian ethics that sought to explain each 'altruistic' action by the pleasure (or avoidance of pain) that it supposedly must give to the individual. Spencer, Haeckel, Karl Pearson (1857–1936), and others sketched out similar theories, acknowledging the variability of human morality by their emphasis on the shaping of instincts by progressively more complex human institutions.

The authors now recognized as founders of social and cultural anthropology, including E.B. Tylor (1832–1917), Franz Boas (1858–1942), and Emile Durkheim (1858–1917), emphasized the variability and adaptability of human customs in contrast to instinct theory. For example, in his foundational *Primitive Culture*, Tylor (1871) argued that phenomena, such as bow hunting or stone tool making, should be explained by selection and gradual improvement of the objects available to humans in their local environments and by imitation of others, rather than by hunting or tool-making instincts. In opposition to this growing ethnological literature, other evolutionists such as Edvard Westermarck (1862–1939) argued that the true motivations for social conduct come from underlying instincts and sentiments. Ignoring these motive powers, Westermarck (1891) argued, leads to a problematic, 'mechanical' treatment of human customs because it seeks to explain social phenomena primarily by social antecedents (a methodology that Durkheim explicitly championed). Consequently, Westermarck's *The History of Human Marriage* relied heavily on notions of parental and sexual instincts to explain the biological foundations of human marriage customs.

The notion that collective behaviors could be explained by attributing them to more-or-less definite instincts was hugely influential in the social sciences of the late nineteenth and early twentieth centuries. Gustave Le Bon (1841–1931), Wilfred Trotter (1872–1939), and others, for example, used notions of instinct to explain the irrational behavior of crowds, and other authors sought to provide an ultimate ground for social behavior in quasi-instinctive, general tendencies to 'imitation,' 'suggestion,' or 'consciousness of kind.' Theories of 'aggressive' or 'pugnacious' instincts proliferated as purported explanations of World War I, although much of this literature was criticized by later social psychologists for the seemingly arbitrary or unprincipled use of 'instinct' as an explanatory device. In economics, authors including Thorstein Veblen (1857–1929), E.A. Ross (1866–1951), and Carleton H. Parker (1878–1918) drew on instinct theory to criticize the structure of industrial production (although they, too, tended to rely on a somewhat metaphorical notion of instinct). They argued that modern economic organization does not permit the greater number of workers sufficient opportunities for the expression of natural impulses such as creativity. Earlier critical anticipations of this argument came from utopian socialist Charles Fourier (1772–1837), who envisioned an emancipatory social order centered on the fulfilling expression of natural impulses for all, and anarchist Mikhail Bakunin (1814–76) who claimed, in opposition to Marx, that men's instinctive need for freedom would impel the masses to social revolution.

The author who sought to ground the social sciences most thoroughly in an analysis of instinct, and who was consequently a frequent target of criticism, was William McDougall (1871–1938). In *An Introduction to Social Psychology* and subsequent works McDougall (1908) argued that social science must be based on an adequate theory of the impulses and motives that sustain and regulate conduct, the so-called "springs of human action." He sought to prevent the social sciences from making the 'ad hoc' assumptions about the nature of the mind or over-generalizing from a particular set of human

motivations as authors had done in the past, and instead to elaborate a synthetic "dynamic, functional, voluntaristic" approach consistent with comparative and evolutionary natural history. He argued that the 'reflex' understanding of instincts only took account of the physiological movements to which instincts give rise, without explaining the 'mental processes' of instincts, themselves. Building from the 'appetitive' or 'impulse' view and from 'faculty' psychology, he argued that instinctive behaviors must be understood to involve cognition of objects, emotion or feeling with regard to the objects, and conative striving toward or away from those objects that regulate the onset and course of behaviors. Thus, the ultimate impetus and end of all human activity, even the most 'passionless' thought, may be found in these instinctive impulses if defined in McDougall's encompassing fashion. McDougall listed what he considered the 'principal' human instincts, which varied somewhat across his work but typically included flight, repulsion, curiosity, pugnacity, self-assertion, self-abasement, parental, reproductive, gregarious, acquisitive, and constructive instincts. Each is directly connected with identifiable emotional states and actions. McDougall explained the vast array of human behavioral tendencies as resulting from the ramification and organization of these instincts in the course of social conduct. His work was drawn upon by a wide variety of writers in the social sciences, psychology, education, and ethics in the early twentieth century, because it appeared to give a principled and comprehensive theory of human motivation.

Criticisms and Alternatives

Among the most prominent early critics of instinct theory in the human sciences were the Behavioral psychologists. In the late 1910s and early 1920s, critiques of instinct were published by Knight Dunlap (1875–1949), Z.Y. Kuo (1898–1970), E.C. Tolman (1886–1959), and Ivan Pavlov (1849–1936), who elaborated themes from the earlier work of Spencer, James, Loeb, and others. Dunlap's work (1919, 1922), in particular, asserted that lists of specific instincts do not represent fundamental, substantively distinct, psychological processes. Instead, these categorizations vary according to the given author's judgment of the classes of 'ends' served by the behaviors (e.g., if a behavior seems to be connected with acquiring sustenance, then it is supposed to result from a feeding instinct). Any list that suits the author's purposes is as valid as any other and no list could be proven to provide a mutually exclusive and exhaustive classification of the observed organism's behaviors. The most systematic analysis of this point was in sociologist L.L. Bernard's (1924) monograph study, which demonstrated from an examination of discussions of instinct in 500 scientific works that no general consensus could be derived.

Second, the observable phenomena explained by instinct could also be explained by notions of 'reflex' or 'habit,' which these authors thought had better claims to being scientifically rigorous concepts. Explaining a behavior as 'instinctive' had the disadvantage of mentalistic or even metaphysical connotations. Any observed behavior was, according to the Behaviorists, obviously the product of both acquired and inherent capacities and a focus on the inherent factors prevents inquiry into the learned and proximate antecedents of the behavior (especially the "conditioning of reflexes" which was the focus of much Behaviorist research). Although John B. Watson (1878–1958) is identified as the primary opponent of instinct theory in many subsequent discussions, he developed his adamant anti-instinct stance as a result of his detailed studies of human infants in the 1920s with Rosalie Rayner, later his wife (1898–1935), and in response to the criticisms of other Behaviorists. Indeed, in his early work on animal psychology, Watson had even proposed his own classification of definite instincts. B.F. Skinner (1904–90) later added to the Behaviorists' critique by arguing that instinct was at best an 'explanatory fiction' or tautology, in that it 'explained' observed behavior by inventing an unobserved faculty or force that tended to produce the corresponding behavior (e.g., humans fight because of an instinct to fight).

An overlapping set of criticisms came from the social science literature of the same period, led by Ellsworth Faris (1874–1953), C.E. Ayres (1891–1972), Charles H. Cooley (1864–1929), John Dewey (1859–1952), and L.L. Bernard (1881–1951). According to these authors, the profound diversity of human customs concerning even such fundamental biological processes as nutrition or procreation, as witnessed in the growing record of cross-cultural studies, could not be explained by a finite set of native instincts. Cooley (1922) in particular, posited that if scientists begin not with the assumptions of individualist psychology but from the premise that human nature is essentially social, there is no need to postulate particular instincts as the special motives of collective behavior. Then, to the extent that there are apparent internal drives motivating human behavior, they could be shown to be products of the personal histories of interactions between individuals and their social environments. Faris and Bernard also pointed out that recourse to instinct tends to mean explaining behaviors in broad, general classes rather than accounting for individual temperamental differences, and such explanations have controversial ethical and pedagogical implications, including an affinity with theories of 'racial characteristics' and the 'standardization' of educational practices. In place of instinct theory, social psychology was dominated from the 1930s by the notion of 'attitude,' especially in the United States, which emphasized explanation by concrete, personalized motives that were more easily recorded, analyzed, and explained, than classes of abstract, uniform instincts.

Since the 1930s, instinct theories have fallen out of favor as explanations in the behavioral and social sciences, while alternative understandings of human motivation have developed. In addition to notions of conditioned reflexes, attitudes, and drives, these include work on the internalization of social expectations; cybernetic feedback theories of behavioral systems; concepts of bounded rationality and uncertainty in decision making; phenomenological or contextualist theories of intentionality; and many others. Alternative vocabularies, without a notion of instinct, have also developed to conceptualize the relationship between the body and social conduct, including terms such as 'body-politics,' 'practice theory,' and 'life-course theory.'

Still, several attempts have been made to rehabilitate a notion of instinct in explaining human behavior. Most

notable among these is the work of 'ethologists,' especially Niko Tinbergen (1907–88) and Konrad Lorenz (1903–89). Tinbergen (1951) and Lorenz (1957) drew upon their work on the native behavioral capacities of lower vertebrate and invertebrate animals to add a new level of sophistication to 'appetitive' theories of instinct. Although humans do not have the same reliance on 'fixed action patterns' as do other animals, they may have some of the same instinctive mechanisms, such as 'imprinting,' that would contribute to the explanation of how human behaviors are learned and develop.

Indeed, the ethologists influenced some work in 'evolutionary anthropology' regarding apparently innate human behavioral tendencies such as territoriality and aggressiveness, as well as work in 'sociobiology' on the biological basis of human prosocial behaviors. In psychology, John Bowlby (1907–90) articulated an influential 'attachment theory,' which draws significantly from the ethologists in arguing that connections between caregivers and infants are based evolutionarily on imprinting like mechanisms. In this work, he noted that as an adjective, 'instinctive' may be useful as a description, even while 'instinct,' as a noun denoting definite behaviors, is problematic. Likewise, Abraham Maslow (1908–70) developed a theory of the 'hierarchy of needs,' positing that human needs are 'instinctoid,' while also arguing that human behavior expresses resistance to, and control of, such impulses in pursuit of higher goals. Indeed, calls to take into consideration the biological nature of human behavior typically have not sought to supplant a one-sided social determinism with biological determinism, but rather to bring these factors together into a broader synthesis.

Another recent literature has developed around theories of psychological 'nativism,' especially the apparently innate aspects of human perception and language capacities. Steven Pinker (1994) explicitly posited that humans possess a unique 'language instinct,' on the basis of the work of Noam Chomsky and others regarding the 'universal grammar' posited to underlie all human language. Still, the growing literature in cognitive science has tended to eschew a notion of 'instinct' and instead has elaborated detailed neurobiological and functional explanations of cognition and behavior. Other lines of investigation have introduced yet another set of explanatory principles based around 'genomics,' and increasingly, 'epigenetics,' to explain the heredity of human behavior and the relationship between biological organisms and the environment. Although these new fields may ultimately revive interest in theories of instinct, they may also have the effect of supplanting that older literature with an entirely different language, viewed as more scientifically productive.

Institutionalism

Abstract

The study of political institutions has moved back into center stage in political science. The study of political institutions and their consequences for political choice and development has moved to center stage in the study of politics. The article first surveys the history of institutionalist thought, then explores several different types of institutionalist theory, and, finally, suggests the central analytical agendas of modern institutionalist theory. The article examines how and why both history and institutions matter for politics and emphasizes the importance of 'ideas' for understanding political change.

The study of political institutions has moved back into center stage in political science. Whereas only a few years ago, institutions were mostly casually mentioned in most political science research, today they are a central focus of attention. This change is not simply a change of language or the catching on of a new popular phrase or academic fad. Instead, these changes represent an important development in evolution of political science theory and intellectual focus.

The following article surveys the history of institutionalist thought, explores several different types of institutionalist theory, and suggests the central analytical agendas of modern institutionalist theory.

What Are Institutions?

In the broadest sense, institutions are simply rules. As such, they are a foundation for all political behavior. Some are formal (as in constitutional rules), some are informal (as in cultural norms), but without institutions, there could be no organized politics. Indeed, absent institutions, and there could be no organization at all. To understand this point, simply attempt to consider a world in which there were no rules: In this Hobbesian hell, individuals would be forced to 'invent' communication every time they encountered another individual. In this sense, then, if we study social interaction, we study institutions. This does not suggest, however, that all social scientists are 'institutionalists.'

Institutionalism

The 'institutionalism' specifically examines the ways in which institutions structure social and political behavior (North, 1990). This burgeoning body of literature argues that policy, politics, and behavior can only be understood in the context of the institutions in which they take place. Thus, for example, Ellen Immergut argues that variations in national health insurance systems are best explained by variations in national political institutions (Immergut, 1998). Similarly, Bo Rothstein shows that Sweden's high union density is best explained by the 'Ghent' unemployment insurance system, which gives workers powerful incentives to join Swedish unions (Rothstein, 1992). Even more broadly, Douglas North suggests that the very success of Western political economic model is rooted in the peculiar institutions developed in these societies (North, 1990).

The central tenet of this new institutionalism is that institutions are not neutral to policy outcomes. As Peter Hall has suggested, "On the one hand, the organization of policy-making affects the degree of power that any one set of actors has over policy outcomes…. On the other hand, organizational position also influences an actor's definition of his own interests…in this way, organizational factors affect both the degree of pressure an actor can bring to bear on policy and the likely direction of that pressure" (Hall, 1986: p. 12).

In sum, institutions define the rules of the political game, and as such they define who can play and how they play. Consequently, they ultimately can shape who wins and who loses. If politics is the study of who gets what, when, and why, then institutionalists argue that institutions should be at the heart of that study.

A Brief History of Institutionalism

Institutionalism has a long-established tradition among those interested in politics and political outcomes. Plato's *Republic* is a comparative study of institutions. Similarly, Aristotle's central concern in *Politics* is which kinds of political institutions will produce the best outcomes. James Madison must clearly also be seen as an early American 'institutionalist' in that he was specifically concerned with which kinds of institutions would produce the best political outcomes and how the specific design of institutions would shape political outcomes.

Political scientists have also long been interested in institutions. Indeed, in its early years, political science meant the study of political institutions (Wilson, 1891). But, with some important exceptions (Herring, 1940; Key, 1947), early political science was often more descriptive than analytical. 'Comparative politics,' in particular, consisted mostly of detailed configurative studies of different legal, administrative, and political structures. In the immediate post-War years, a new generation of political scientists attempted to make the study of politics more 'scientific.' For many, this effectively meant that political science ought to model itself on the 'hard sciences,' which they believed was fundamentally a deductive process. Thus, rather than studying the details of political life and

inductively uncovering the patterns of behavior and action, political 'science' should be a deductive science that seeks to discover of the general laws and fundamental forces that lie behind political action. Focusing on particular institutions, proponents of this intellectual agenda implied, was 'atheoretical.' Concomitant with the push for more abstract laws, political scientists were disillusioned by the failure of parliamentary institutions in inter-War Weimar Germany (and later in postcolonial Africa) to prevent these polities from devolving into authoritarianism. Clearly, many argued, there were bigger, more important, indeed more fundamental forces at work in politics and development than political institutions. These forces, they argued, should be the focus of political science.

Thus, behavioralist, functionalist, and Marxist perspectives took leading roles in political science theory-building through most of the 1960s and 1970s. As a consequence, institutional analysis diminished in prominence, particularly in comparative politics. For functionalists, political institutions were simply seen as organizations created to fulfill the systemic needs of society. As such, political institutions were neither important nor interesting. For behavioralists and Marxists, political institutions were simply arenas in which political battles were fought out. While Marxists saw the relevant groups as classes and Pluralists saw them as more narrowly defined, neither theoretical perspective paid particular attention to the structure or character of the institutions themselves. The real meat of politics, they argued – and the keys to understanding political outcomes – was found in the articulation of group interests. Though this was rarely explicitly stated, implicit in these theories was the assertion that if politics or policies differed between societies, this difference was surely the result of different constellations of group and class interests or preferences (Almond and Verba, 1963; Verba, 1967; Miliband, 1969).

It was not the case, however, that all political scientists had abandoned the study of institutions. Indeed, many of the most widely read scholars in American politics maintained an explicitly institutional emphasis (Schattschnieder, 1960; Greenstein, 1963). In comparative politics as well, several political scientists continued to examine political institutions and their effects on political outcomes (Ekstein, 1960; Bendix, 1964; Huntington, 1968), even while they sometimes had to defend their 'inductive' approach from the challenge that it was not 'scientific' (Przeworski and Teune, 1970). For these scholars, it was self-evident that if one wanted to understand what government does, one needs to specifically study the institutions through which it acts.

It was probably in comparative politics that the search for 'grand theory' had its most significant impact. It may be for this reason that a self-conscious return to 'institutionalism' was most forcefully articulated here. Among the first group of scholars to move in this direction was Peter Katzenstein and his colleagues, who sought to explain why several advanced capitalist states responded so differently to the oil shock of the 1970s. The answer, they concluded, was found in the differing institutional structures in these polities and the consequent patterns of economic policy pursued in each nation (Katzenstein, 1978). Similarly, Theda Skocpol's study of social revolutions also concluded that one could not explain the course of a country's revolution without examining the nature and structure of the state against at which these revolutions were aimed (Skocpol, 1979).

Soon a new 'state-centered' approach emerged in comparative political inquiry. These scholars forcefully argued against the behavioralist and Marxist 'grand theory' emphasis, then dominant in the study of comparative politics. Instead, they suggested, political outcomes were shaped and structured by the specific actors and their position in the state. One should not treat the state as a neutral 'black box' through which group or class interest was simply translated (Evans et al., 1985). Instead, the state had independent interests and agendas, which were separate and different from the interests and preferences of classes and interest groups that made up society.

Of course, it did not take long for these scholars to discover that 'the state' is too broad a concept and too varied a set of institutions to be 'taken seriously' without being broken down. To make analytic sense out of the insights, scholars began examining institutions more carefully. If state institutions 'matter,' they argued, then why should this not be equally true of institutions outside the boundaries of the executive state? With these questions, 'the new institutionalism' was born.

Three Types of Institutionalism

Today, three different intellectual approaches lay claim to the term 'institutionalist' (Hall and Taylor, 1996). Each grows out of a different academic discipline and attempts to integrate these different analytic traditions into the understanding of politics. Sociological institutionalism, as its name implies, grows out of sociology and the study of organizations (Selznick, 1949). These scholars have been centrally interested in understanding culture and norms as institutions. These scholars emphasize 'folkways,' 'patterns of behavior,' and 'cognitive maps' and argue that these social institutions are critical for understanding the structure of social, political, and economic interactions (March and Olsen, 1989; DiMaggio and Powell, 1991). Building on upon their analyses of complex organizations, these scholars show the relationship between formal institutions and the structure or patterns of behavior and beliefs. They argue that these informal institutions are core to any understanding of the nonrational aspects of human communication and exchange.

'Rational choice (RC) institutionalism,' taking its lead from economics, emphasizes quite different sets of institutions and their effects. RC scholars attempt to apply the formal logic and methods to the study of politics and history and often explicitly eschew the more 'mushy' or less precise variables such as norms and beliefs. Instead, basic assumptions are made about human behavior and motivation in order to uncover and examine the basic laws of political behavior and action. Scholars in this tradition argue that once these laws are discovered, models can be constructed that will help us understand and predict political behavior (Levi, 1988). In their deductive model, RC scholars look to the real world to see if their model is right (test the model). For these scholars, understanding real outcomes is not the first point – creating, elaborating, and refining a theory of politics is (Weingast, 1996).

The implications of this scientific orientation are substantial. Morris Fiorina, a highly regarded RC scholar at Harvard,

put the issue in the following way: "most PTI scholars are not as interested in a comprehensive understanding of some real institution or historical phenomenon, so much as in a deeper understanding of some theoretical principle or logic … [F]or most PTI scholars, breadth trumps depth; understanding 90 percent of the variance in one case is not as significant an achievement as understanding 10 percent of each of nine cases, especially if the cases vary across time and place" (Fiorina, 1995: pp. 110–111).

The third 'new institutionalist' approach emerges out of what might be considered a more traditional political science. Consequently, it has a quite different aim: Historical institutionalists are primarily interested in understanding and explaining real-world events and outcomes. As with the other approaches noted above, scholars working in this tradition also argue that one cannot explain particular historical outcomes without specifically examining the way in which the political institutions have shaped or structured the political process (Steinmo et al., 1992). But, unlike RC scholars, in particular, historical institutionalists came about their 'institutional' arguments inductively after testing a variety of alternative theories (i.e., Marxist, structural functionalist, culturalist, and rationalist) against the outcomes they observed. In other words, historical institutionalists are first interested in explaining an outcome (say, e.g., why France and Britain have pursued such different styles of industrial policy (Hall, 1986) or why some welfare states generate more popular support than others (Rothstein, 1998)); they then proceed to explore alternative explanations for the outcomes they observe.

Historical institutionalists do not argue that institutions are the only important variables for understanding political outcomes. Quite the contrary, these scholars generally see institutions as intervening variables (or structuring variables) through which battles over interest, ideas, and power are fought. Institutions are thus the focal points in critical junctures in a historical path analysis because political battles are fought inside institutions and over the design of future institutions.

Taking *History* Seriously

These insights had important implications, both for what we study and for how we study it. Historical institutionalists study history because they believe history matters, not merely to increase the reference points for analysis (as is done in time series analysis). There are at least three important ways in which history matters. First, political events happen within a historical context, which has a direct consequence on the decisions or events. An early example of this is the seminal work of Alexander Gerschenkron, who argued that *when* a country industrializes necessarily affects *how* it industrializes. He shows us why latecomers cannot go through the same long trial-and-error process followed by early developers. (An example outside politics may prove illustrative. Many of us recognize that firstborn children have a very different developmental experience than second (or later) children. Not only are the parents more experienced after the first child, they are also taking care of more than one child at a time. Finally, and equally importantly, subsequent children grow up in a home where there are older siblings – something the first child, by definition, cannot do.) In other words, the process of industrialization is essentially different for late developers than for early developers. This is a huge insight that is easily missed in large-scale quantitative, cross-national comparisons, which very often pool data across continents and time periods and treat the time/place as inconsequential (or assume that it will 'wash out' of the analysis).

The second reason why history matters is that actors or agents can learn from experience. Historical institutionalists understand that behavior, attitudes, and strategic choices take place inside particular social, political, economic, and even cultural contexts. Rather than treating all political actions as if they are fundamentally the same, irrespective of time, place, or context, historical institutionalists explicitly and intentionally attempt to situate their variables in the appropriate context. Thus, by deepening and enriching their understanding of the historical moment and the actors within it, they are able to offer more accurate explanations for the specific events that they explore than had they treated their variables outside the temporal dimension.

E.E. Schattschneider's early work on tariff policy showed how political choices made at time A have important consequences for time B. In this work, he famously argued that "new policies create new politics." Following Schattschneider, Paul Pierson has shown in several important works, *how and why* policy choices at one point in time affect choices at subsequent points in time. Similarly, Esping-Andersen pointed out in his seminal *Three Worlds of Welfare Capitalism*, how, given the fact that we live in modern welfare states with unemployment insurance, health insurance, pension programs, and the like, the existence of the welfare state is a fact of modern political life that itself *shapes* politics, expectations, and policy in the countries that have developed it (Esping-Andersen, 1990).

Finally, again as Pierson has shown, expectations are also molded by the past (Pierson, 2004). While some might point to America's adventure in Iraq as a simple product of power politics and/or the demand for oil, a historical institutionalist would more likely look to the patterns of past victories for an understanding of why this country reacted in the way it did to the 9/11 attacks. Certainly they were mistaken, but there should be little doubt that America's past successes in Germany and Japan – to say nothing of their perceived victory over Communism at the century's end – led policy makers in the administration to believe that they could assert American power and bring successful capitalism and democracy to a former dictatorship.

In sum, for historical institutionalists, *history is not a chain of independent events*. There is more than the temporal dimension implied in this basic point. Taking history seriously ultimately means that the scholar is skeptical of the very notion of variable independence. Instead, acknowledging the importance of history suggests an explicit awareness that important variables can and often do shape one another. Historical institutionalists, more than political scientists in some other traditions, are explicitly interested in these interactive effects on the interdependence of multiple causal variables.

Historical institutionalists are something like an environmental biologist, who believes that in order to understand the specific fate of a particular organism or behavior, he or she

must explicitly examine that organism or its behavior in the ecology or context in which it lives. This implies a different scientific ontology than that commonly found in the hard sciences of physics and chemistry. At the root of evolutionary biology is the assumption that the objects of analysis – living organisms – are fundamentally different from inanimate matter. While objects in the physical world often adhere to constant 'laws' of nature, biological organisms often defy attempts to reduce them to their essential components because of their complexity. Thus, as eminent evolutionary biologist Ernst Mayr points out, the development of biology as a science has required an investigation of 'additional principles' that applied only to living organisms. He argues, "This required a restructuring of the conceptual world of science that was far more fundamental than anyone had imagined at the time" (Mayr, 2004: p. 26).

Historical institutionalism represents something like this ontological move in social science. In order to understand historically specific events and long-term political outcomes, one could not strictly apply methods and epistemologies drawn from the study of invariant variables that have fixed relationships across space and time. This, of courses, does not mean that it is not science – unless one's definition of science would exclude biology as well – rather, it implies that the scientific methods applied should fit the subject being studied.

Ideas, Institutions, and Change

To argue that 'institutions matter' is by now taken as common sense. Today, it is widely recognized that institutions provide stability in political life because they structure political choices. This is because when we know the rules, we are more likely to know how to interact and how to behave. Indeed, when we know the rules, we adapt our behavior accordingly. The more difficult and interesting questions arise when we ask the following: (1) Why do people follow rules? (2) How do we explain institutional change? (3) if institutions are so important, what role is left for human agency and ideas?

Early institutionalist scholars drew insights from evolutionary theory of 'punctuated equilibrium' to explain institutional change (Steinmo et al., 1992). In recent years, however, there has been growing interest in explaining the *endogenous* sources of institutional change. A number of scholars have mapped out different types of institutional change in different contexts (Streeck and Thelen, 2005; Mahoney and Thelen, 2009). These efforts have led to considerable refinement of our understanding of different *types* of institutional change, but are insufficient for explaining *why* institutions change.

The most important contributions to institutionalist theorizing on change have come from those scholars who specifically have tried to examine relationship between human agency and ideas (Campbell, 2002; Lieberman, 2002a; Blyth, forthcoming; North, 2008). Traditionally, institutions (especially those in the RC school) are created by individuals seeking to maximize their individual interests. Ideas, in this view, were simply epiphenomenal or justification for people's 'real' motivation. But such an approach is unsatisfactory, both at the common sense level (we know that human beliefs and ideas matter for our choices) and because these approaches fail to explain how we move from one equilibrium to another.

The interesting questions arise when we look at the interdependent relationships between ideas, institutions, and interests over time. Since none of these factors are static, only through a historical analysis can we learn how they develop, how they change, and why they are so different in different contexts (Lieberman, 2002b). Building on the work of social psychologists such as Amos Tversky and Daniel Kahneman (Kahneman et al., 1982; Kahneman, 2011), institutionalist scholarship is moving toward a more nuanced understanding of the 'social foundations' of human rule following behavior and is attempting to better understand the ways in which human cognitive biases' shape interacts with institutional structures to influence human behavior. Social psychologists have long understood that human beings are social creatures who are not normally individualistic in a meaningful sense. Instead, we are driven to follow social rules and look for social approval. Human beings are more likely to be normative actors, possessing significant cognitive biases, rather than rational self-interested utility maximizers. Appreciating human motivations in this way forces us to consider the interaction of institutional rules, human choices, and eventually, differences in cultural systems.

Finally, institutionalists have begun to argue that we can understand change in evolutionary terms and thus bring some of the insights from evolutionary theory into the study of institutional evolution (Lewis and Steinmo, 2012). Whereas traditional political science has taken a mechanical approach to the study of politics and human affairs (Hall, 2003), an evolutionary approach to institutional change allows one to integrate contingency into the study as well as be more honest with the fact that there are no truly *independent* variables of interest in human affairs. Almost everything that is really interesting and important is instead the product of the complex interaction of multiple factors that interact with each other over time (Streeck, 2010).

Institutionalism and Neo-institutionalism: History of the Concepts

Markus Hadler, Macquarie University, Sydney, NSW, Australia

Abstract

This article discusses the history of neoinstitutional theory. It starts with a definition of the term institution and then discusses the development of neoinstitutionalism in economics, political science, and sociology. It also addresses differences between the main strands of neoinstitutionalism and concludes with a brief overview of the discursive institutionalism.

Early institutionalism and neoinstitutionalism share an interest in the effects and origins of 'institutions.' The term 'institution' however is widely used and this article, therefore, starts with exploring its different meanings. The scientific approach of neoinstitutionalism itself is commonly seen as divided into the three strands rational-choice, historical, and organizational neoinstitutionalism. This classification aligns vaguely with the disciplines of economics, political science, and sociology. The second part of this article, therefore, discusses the development of institutionalism in each of these three disciplines. This historical overview is followed by a discussion of the differences between these different strands and a description of the most recent development, the discursive neoinstitutionalism.

Institution and Institutionalism

'Institution' is used in various regards and can, according to Immergut (2011), refer to the degree of formalization of social behavior, ranging from casual habits to formal arrangements, to the extent of the collective binding, ranging from traditions and folkways to sanctioned laws, and to the way they are sanctioned, ranging from being self-reinforced to coercion by other entities. Finally, institution can also label organizations such as institutes of scientific study and financial organizations that are charged with the implementation of 'institutions' such as education and monetary instruments. All these aspects have in common that institutions are considered socially constructed and not biological determinants.

In terms of scientific disciplines, early institutionalism refers to approaches in the late-nineteenth and early twentieth centuries and scholars such as Thorsten Veblen or Max Weber. Their main emphasis was on studying the development of larger formal institutions such as legal, economic, religious, and other societal systems. These approaches, however, lost ground in the early decades of the twentieth century, when behavioristic models gained importance. Once shortcomings and inconsistencies in these behavioristic models became obvious, institutionalism was revived, starting in the 1970s.

These new versions of institutionalism share only some of the views of the early institutionalism, despite being labeled 'neo'-institutionalism. A main difference is that neoinstitutionalism considers institutions broader than the earlier scholars and is rather in line with Peter Berger and Thomas Luckmann's definition that "institutionalization occurs whenever there is a reciprocal typification of habitualized action by types of actors." (1966: p. 54). In this regard, the term institution is not limited to formal institutions any more, but emphasizes the experience of an institutional world as an objective reality. There are, however, significant differences within the contemporary 'neoinstitutionalisms' and these differences will be addressed in more detail in the following sections.

Economics

The early institutionalism in economics developed in opposition to the neoclassical view that individuals are rational economic actors and that a few basic assumptions and laws are sufficient to explain economic processes. These conflicting views found their expression in the German Methodenstreit of the late nineteenth century, in which institutionalists such as Gustav Schmoller emphasized that economic processes are outcomes of specific historic developments and embedded in cultural settings, whereas scholars such as Carl Menger represented the neoclassical views. Early American institutionalists such as Thorstein Veblin and John Commons were influenced by this German discussion and shared the interest in the historical development of economic phenomena.

Thorstein Veblen studied in his book *The Theory of the Leisure Class: An Economic Study of Institutions* (1899) the individual overconsumerism, a behavior that violates the assumption of rational, resourceful, and efficient actions. Veblen identified the stratification system and social classes in feudalism as a possible cause of this utility violating behavior. John Commons, in contrast, focused on the transaction, the basic social interaction of two parties. This interaction follows certain rules of conduct, which are also considered social institutions. Commons was particularly interested in the historical development and origin of these institutions and summarized his views on the collective nature of institutions in his 1934 book *Institutional Economics*.

The early institutionalism lost ground in economics over the first decades of the twentieth century, whereas neoclassic views gained influence at the same time. A possible explanation for its demise can be seen in the institutionalists' overemphasis on historical developments and idiosyncratic explanations with little emphasis on theory development. This diminished influence is also reflected in the fact that Ronald Coase's article from 1937, *The Nature of the Firm*, that focused on transaction costs and is now considered a classic

work by neoinstitutionalists, went rather unrecognized for several decades.

It was only in the 1970s, when Oliver Williamson added specific conditions such as increasing transaction costs under uncertainty and individual opportunism to Coase's work, that Coase's early work became more popular. It was also Williamson (1975) who coined the term 'Economic neo-institutionalism.' Williamson's work, however, shows an important difference to the early institutionalism and highlights its closeness to neoclassic views: Williams assumes given individual preferences and does not consider them as being shaped by specific historical developments and a cultural embedding.

This difference is also generally reflected in the contemporary economic neoinstitutionalism, which shares only some assumptions with the early institutionalism. Similar to the early approaches, it focuses on the effects of institutions and their origin and evolution. It considers "Institutions … written and unwritten rules, norms, and constraints that human devise to reduce uncertainty and control their environment" (Menard and Shirley, 2005: p. 1). It, however, also adopted the neoclassic assumptions of scarcity and competition – without the notion of perfect information and instrumental rationality.

A different strand within economics focuses on the macro-development of societal institutions and thus is close to the historical institutionalism, which will be discussed in the political science section. A prime example in this regard is the economic historian Douglas North, who, for example, discussed the types and forms of economic exchange in different societies and how its patterns and structures have evolved over time (North, 1991).

The historical development of contemporary economic institutions is also addressed in evolutionary economics. Richard Nelson and Sidney G. Winter's book *An Evolutionary Theory of Economic Change* (1982) that describes changes in routines and technology can be named in this regard. Despite not explicitly referring to institutions, their research resonates with the ideas of Thorstein Veblen and particularly Joseph Schumpeter – one of the few economists, who continued to work in the tradition of the early institutionalism.

Political Science

Institutional approaches with a focus on descriptions of the roots and developments of legal systems were the dominant approach in political science in the nineteenth and early twentieth centuries. Prominent scholars in this time were J.W. Burgess and the later US president Woodrow Wilson. These scholars produced dense descriptions of legal systems and other political institutions that were guided by moral philosophical accounts and – similar to the early institutionalism in economics – rather scarce in theory building. This approach lost ground in the first decades of the twentieth century when behavioral perspectives gained importance, accompanied by a topical shift to political behavior, voting behavior, and public opinion.

Ideas of these early institutionalists were revived in a reaction to group theories and structural-functionalist theories that were dominant in the 1960s and 1970s and labeled historical institutionalism. Historical institutionalism sees institutions as "… the formal or informal procedures, routines, norms and conventions embedded in the organizational structure of the polity or political economy" (Hall and Taylor, 1996: p. 938).

Among others, the rise of this theory in political science is associated with Theda Skocpol's book *States and Social Revolutions: A Comparative Analysis of France, Russia and China* (1979), which focuses on the social institution 'state' and its influence on social change. Its interest in the development of modern institutions resonates with the ideas of early institutionalists, but differs as it does not follow normative considerations. Outcomes are not considered predetermined, but often as unintended consequences. Insofar, there is no necessary trend toward democracy, modernity, and other societal traits. Institutions, however, are not considered the only determinant of social change. Factors such as dominant ideas and societal affluence are taken into account as well.

Despite being a reaction to group theories and structural-functionalism, the historical institutionalism nonetheless incorporated ideas of these theories (Hall and Taylor, 1996). It kept the assumption of rivalry and scarcity. In this regard, power differences between groups is a central concern and historical institutionalists frequently focus on the role of institutions in giving some groups more power than others. Similar to structural-functionalists, historical institutionalists consider the polity a system of interrelated parts, but rather consider its influence on individual behaviors than seeing individual traits and beliefs as the basis of this system.

As far as the relationship between the individual and institutions is concerned, historical institutionalism is located between the rational-choice and sociological neo-institutionalism (Hall and Taylor, 1996). Scholars use both a rational-choice related approach, where institutions provide information that can reduce the uncertainty for actors that make rational choices, and a cultural approach, where institutions are considered cognitive templates that frame the choices of an individual. While the former considers individuals as utility maximizers, the latter sees them as individuals that select or satisfy different options.

Alongside with this historical institutionalism, a rational-choice focused neoinstitutionalism that extents economic institutionalism to political science has developed as well. The rise of this rational neoinstitutionalism was inspired by the paradox observation that the voting outcomes and agreements within the US congress were driven by relatively stable majorities, whereas rational-choice theory would predict constantly changing alliances, given the many different interests of legislators (Hall and Taylor, 1996). An explanation of these stable outcomes is 'institutions' as they are considered to "lower the transaction costs of making deals" (Hall and Taylor, 1996: p. 943). These ideas have been employed well beyond the US congressional outcomes and applied to the influence of laws, political institutions, and the evolution of law.

Sociology

Institutions have been discussed within sociology in more detail than in economics and political science and, thus, the perspectives of various classic European and American

sociologists are reflected in contemporary neoinstitutionalism (see Scott, 2001).

Among the European roots, Karl Marx's view that the material world and the associated beliefs and norms determinate the social construction of reality, Emile Durkheim's emphasis on social facts that govern human behavior, and Max Weber's approach that considered economic institutions as specific historical developments, but was also in favor of theory building, can be named. Among the American sociologists, Herbert Spencer's and William Sumner's division of societies into different segments, Everett Hughes' studies of the institutional structures of the workplace, Talcott Parsons' system of action, and Peter Berger and Thomas Luckmann's theory of the social construction of reality can be named.

A first important shift toward the contemporary sociological neoinstitutionalism was the application of these classic thoughts to organizations – an aspect the early institutionalists with their focus on broader social phenomena such as political and economic systems did not consider explicitly. The impetus to focus on organizations came via Robert K. Merton and, particularly, his student Philip Selznick. Selznick's (1949) study of the Tennessee Valley Authority (TVA) can be considered a classic work in this regard. The TVA was founded by the US government to aid the underdeveloped areas between Kentucky and Alabama by acquiring private land to control floods and producing electric power. The organization co-opted local actors, which turned out to undermine its mission. Important features of this study are a focus on unintended consequences, political influences, and struggles, also from outside the organization, and not just a narrow view on the economic environment.

In the consecutive decades, however, organizational sociology was dominated by contingence theory, resource dependency, and population ecology with a narrower focus on the economic environment (Senge, 2007). Contingency theory, for example, focuses on technical and economic circumstances and which form of organization survives; resource dependency on organizations that exchange resources and, even more, resources that have monetary value; and population ecology on the adaption of organizations. In the late-1970s and early 1980s, the interest in institutions gained again importance. This new institutionalism revived perspectives of the classic approaches and added ideas developed in philosophy and social psychology.

The relationship of neoinstitutionalism to philosophy comes from phenomenology, a strand of philosophy that goes back to the German scholar Edmund Husserl in the late-nineteenth century. His ideas were picked up by various scholars and led, for example, to the development of philosophical anthropology, an approach that considers humans as both creatures and creators of their social environments and institutions as a replacement for biological determinants. Phenomenology found its way into sociology via the Viennese scholar Alfred Schütz, whose social phenomenology was based on everyday knowledge. Sociologists such as Harold Garfinkel, Peter Berger, and Thomas Luckmann continued these thoughts and the focus on the semiotic functions of culture with an emphasis on knowledge and belief systems turned out to be central to sociological neoinstitutionalism.

Parallel, neoinstitutionalism also integrated developments of social psychology that emphasize the cognitive processes of individuals. Individuals are considered information processers that use particular 'scripts' and 'schemas' as templates in this interpretation. This view complements the sociological emphasis on the context that sees individuals as rather passively exposed individuals. It is also reflected in the organizational sociology definition of institutions: "Institutions are socially constructed, routine-reproduced (ceteris paribus), program or rule systems. They operate as relative fixtures of constraining environments and are accompanied by taken for granted accounts" (Jepperson, 1991: p. 149).

In sum, the old and the new institutionalism in sociology share various perspectives, but have also clear differences (see DiMaggio and Powell, 1991: p. 12ff). Both are distant to rational actor models of organizations, emphasize the influence of the organizational environment, and consider the role of culture in shaping organizations. As for differences, early institutionalism focused on the political influence and resulting constraints through trade-offs implied by these choices, whereas the new institutionalism emphasizes the influence of common understandings that are taken for granted. Furthermore, the old institutionalism focuses on informal interactions within organizations to explain irrational decisions, whereas the new institutionalism considers the organizational structure itself irrational and decisions as driven by cultural accounts from outside the organization. It has also a broader understanding of organizational environments and does not limit them to the local context. This is reflected in the new view that institutionalization occurs outside the organization, within industrial sectors, or even at the societal level. The classic organizational institutionalism, in contrast, located these processes within the organizations.

Ideas developed within this new sociological institutionalism have been extended beyond the narrow scope of economic organizations. Within sociology, the world society – also world polity – approach can be named in this regard (see Meyer et al., 1997). This approach discusses the diffusion of global ideas and how they influence states, organizations, and other constituents around the world. This view is reflected in the hypothetical example Meyer et al. discuss: A newly discovered island would be immediately visited by consultants of various international organizations and soon develop an organizational structure that resembles the structure of most states around the world.

Differences between the Three Main Areas

An obvious difference between these approaches, first, arises from the nature and topical areas of their disciplines. Less obvious, differences also emerge regarding the role of the individual (Schofer et al., 2012). The economic rationalism operates under a rational actor assumption and asks why individuals enter institutional arrangements and studies the consequences of these arrangements on behaviors. Historical institutionalism focuses on macrodevelopments and considers the evolution of different institutions, but places less emphasis on their influence on the individual (Hall and Taylor, 1996). The sociological neoinstitutionalism sees individuals as

constituted by institutions, thus asserting that even the choices and ideas individuals perceive are shaped by the prevalent institutions (Jepperson, 1991).

Another difference comes from the question of the origins of institutions. Both sociological and historical institutionalisms assume an existing world of institutions. The question then arises how new institutions are drawn from this existing repertoire. As Hall and Taylor (1996) point out, the sociological view places less emphasis on the role of agents in implementing institutions, while the historical institutionalism places more emphasis on existing power relationships that favor some actors over others in the process of creating new institutions. Rational-choice institutionalism, on the other hand, emphasizes the functions of institutions, and the reason why they were kept up.

Discursive Institutionalism

Recently, a fourth strand of neoinstitutionalism has developed that is labeled discursive institutionalism or constructivist institutionalism (Schmidt, 2008). This approach focuses on the role of ideas and is considered a more dynamic approach than the three other neoinstitutionalisms. Rational-choice, historical, and sociological neoinstitutionalism have a tendency to emphasize the external role of institutions in shaping individual behaviors, organizational goals, and other outcomes. The discursive approach, in contrast, considers institutions as a process in which agents create and maintain institutions. In this regard, discursive institutionalism studies the development of ideas, places them in a specific context, and scrutinizes the way they are conveyed. In its application in political science, it is employed to two basic forms of discourse: between politicians (coordinate discourse) and between politicians and the general public (communicate discourse). In studying these processes, research in the area of discursive institutionalism often integrates insights from the other three neo-institutionalisms and thus could be also considered a complementary approach.

Abstract

Institutions induce regularity and stability in human interaction. All human societies have developed a variety of institutions that deal with recurrent basic problems in social life; for example, institutions regulating kinship and family life and economic and political institutions. There are many different kinds of institutions some of which are described in the article. To explain the emergence of institutions and of institutional diversity is one of the most important tasks in social theory. Functionalist accounts point out the beneficial effects of institutions. It is, however, particularly important to explain why inefficient institutions emerge and persist.

Institutions induce regularity and stability in human interaction. All human societies have developed a variety of institutions that deal with recurrent basic problems in social life; for example, institutions regulating kinship and family life and economic and political institutions. The *concept* institution entails duality in a certain sense. Institutions are, on the one hand, *constraints* on human action. They provide 'rules of the games' actors are playing. On the other hand, institutions are results of human action and interaction. Institutions can then be defined as *outcomes* of social interactions such that the agents' behavior becomes stable because it is consistent with an equilibrium. Thus, there is a 'structural' and an 'agency' aspect in the concept of institutions. Institutions can be defined as shared beliefs that certain rules will be used in specific recurrent situations by almost all other agents. Given these beliefs, a behavioral regularity will be observed. Institutions are relevant in various societal domains and on different levels. Social theory deals with the *explanation* of institutions and of institutional diversity within and across societies. Many sketches of explanations of institutions emphasize the *effects* (or functions) of institutions. However, these (quasi) functionalist accounts are not sufficient to explain the *emergence* of institutions.

The Concept 'Institutions'

In everyday language and in the social sciences, the term 'institutions' is used in a broad and sometimes amorphous way. It is quite common to denote organizations such as governments, business firms, political parties, schools, and public administrations as 'institutions.' For example, Goffman (1961) coined the term 'total institutions' to characterize certain types of organizations like prisons, monasteries, and mental hospitals, which tend to 'mortify' the inmate's self. On the other hand, the term 'institutions' also, more specifically, refers to rules and other constraints of human interaction. 'Institutions' in this sense include conventions (e.g., traffic rules), as well as informal and formal social norms. Furthermore, the term is often used to describe complex systems of interrelated norms and the organizations and other factors that enforce these normative standards (Greif, 2006). Modern law can be considered as a set of formal norms proscribing or prescribing certain actions. Another aspect of the law is that it employs (mainly negative) sanctions to punish and prevent deviant behavior. In accordance with Max Weber's terms (1922), the law induces stable regularities of nondeviant behavior via (threats of) sanctions that are employed by a specialized staff of actors. In this sense, the law may be conceived as an organization that enforces certain formal norms.

There is some disagreement about whether or not organizations should be conceptually demarcated from institutions. Greif (2006: p. 30 – italics omitted) defines institutions as "systems of social factors that conjointly generate a regularity of behavior." Besides norms, rules, and beliefs, Greif considers organizations as institutional elements. Other authors (e.g., North et al., 2009, Chapter 1) admit that organizations comprise institutional structures, namely, rules, norms, and beliefs. However, in contrast to institutions, organizations are sets of actors pursuing their goals via coordinated or even centralized decision making. Many organizations can be conceived as collective or corporate actors (Coleman, 1990). Following this line of reasoning, organizations and institutions are distinct: institutions are elements of organizations but organizations include additional components.

Some 'institutions' and social orders like authority systems have 'legitimacy' in M. Weber's (1922) sense. That is, (some of) the involved individuals share the belief that the institutional rules are valid, fair, or obligatory and there is a kind of moral duty to accept them. In cases like these, the institution's stability may be more robust in comparison to institutions that merely depend on self-interest. It seems, however, inappropriate to define institutions by the criterion of legitimacy. The legitimacy of an institution is in general an empirical question and may be a matter of degree.

Another point of disagreement is related to the question of whether institutions can be represented by the rules that prescribe or prohibit certain actions; that is, by linguistic *statements* with deontic ('ought') operators that specify that certain actions should be performed under specific conditions (Ostrom, 2005, Chapter 5). Analyses of the syntax and grammar of institutional statements may be important in institutional analysis, but one should keep in mind that the existence of normative or other institutional statements per se does not guarantee that a stable regularity of behavior will emerge.

The concept 'institutions' is thus used in a dual way. First, it denotes rules, constraints, or norms of human interaction. Second, it describes the resulting stable patterns of interaction

(regularities of behavior) among a set of agents and the social mechanisms generating this outcome. To allude to the modern choice theoretic framework of game theory, institutions are first represented by the rules of the games actors are playing. These rules define, among other aspects, the set of possible actions (strategies) of the agents. They also specify the consequences of the actions (payoffs) and the available amount of information and shared beliefs about each agent's behavior. Given these rules, constraints, and shared beliefs, agents choose an action (strategy) that is individually optimal. The optimal choices will, under general conditions, yield an equilibrium. An equilibrium (in the Nash sense of classic game theory) is a combination of actions (strategies) such that no agent has an incentive to deviate from his or her chosen actions unilaterally; that is, under the condition that the other actors choose their equilibrium actions. The stability of an equilibrium is due to the fact that no (rational) actor could gain by shifting to another strategy unilaterally. Consider now a population of actors who recurrently interact in a social situation governed by the rules of the game. Then it may happen that a specific equilibrium will eventually evolve. In other words, a stable pattern of social interactions may emerge under the constraints of the rules of the game.

An 'institution' can thus be conceived to be the set of constraints or rules that determine the opportunities, beliefs, and incentives of the relevant actors in a given situation. Second, interactions within these rules generate equilibria, which may be stable over time if the situation is recurrent. These equilibrium outcomes can be considered an integral component of the institution. To illustrate, consider a coordination situation. Imagine a time with considerable road traffic (e.g., horse-drawn carriages in the seventeenth century) but no universally accepted rules with respect to keeping left or right. If a central authority (the government) were to create the rule that pedestrians use the right side of the road and horse-drawn carriages use the left side, one source of potential accidents could be avoided, namely, inconsistent mutual reciprocal expectations with regard to the usage of public roads. The rule would, so to speak, 'solve' a coordination problem. A coordination problem can roughly be defined as an interaction with multiple equilibria. In the absence of any rules, precedents, or 'focal points' (Th. C. Schelling), there would be ambiguity with regard to the different courses of action available to road users: should one use the right or the left side of the road? The actors probably do not have intrinsic preferences with regard to the direction of the rule; that is, whether to go right is better than to go left. But they prefer to adopt a rule that gives clear and unique prescriptions and prevents accidents if universally acknowledged, rather than ambiguous rules or rules that are not easily implemented (e.g., the rule that one should determine by chance whether to go right or left). Given that the government has publicly announced a rule, the participants easily form convergent expectations based on shared beliefs with regard to each other's behavior. In other words, an equilibrium of universal rule-oriented behavior emerges as a consequence of individually adaptive or optimizing behavior under the constraints of the rules of the game and of external constraints created by the government. This gives rise to a 'convention.' Following Lewis (1969), a convention may be defined as a behavioral regularity R in a population of agents who recurrently interact in a coordination situation if R is an equilibrium of the recurrent situation and if almost every member of the population prefers to conform to R on the condition that almost every other member of the population conforms to R too.

Conventions arising in so-called pure coordination situations (with no conflict of interest) are self-enforcing. This is so because any individual who deviates from R would punish himself. There is no incentive to break the rule – even if external monitoring and sanctions were absent. The shared belief (expectation) that the rule is universally accepted is confirmed and reinforced in any instance of the recurrent situation and becomes a kind of self-fulfilling prophecy. In other social situations, for example, of the prisoner's dilemma type, there is an incentive to defect. A prisoner's dilemma is a social interaction such that universal cooperation is profitable to everyone, but it is even more profitable to defect unilaterally from cooperation. Cooperation is not an equilibrium situation in the single-shot prisoner's dilemma. In a population of agents who recurrently interact in a prisoner's dilemma, an institution of mutual cooperation may emerge if there is a policing mechanism such that members of the population of agents expect that nonconformity will be punished by (negative) sanctions. The policing or enforcement of cooperation could be achieved under appropriate social conditions due to sanctions that are created by the agents themselves. Of course, intervention by external, third parties (in the sense of Hobbes' *Leviathan*) would be another mechanism that enforces cooperation. Generalizing Lewis's concept of convention, a social institution can be defined as a regularity in the behavior of the members of a population that "specifies behavior in specific recurrent situations, and is either self-policed or policed by some external authority" (Schotter, 1981: p. 11; italics omitted). The self-enforcement of an institution may be due to the fact that the regularity is an equilibrium of a coordination problem. If the recurrent situation has similarities with a prisoner's dilemma, however, an equilibrium of cooperative behavior may result from self-created sanctions (e.g., of the 'tit for tat' type, cf. Axelrod, 1984) or from policing by an external authority or from other factors. The concept 'social institution' in this sense includes conventions as a special case, and also formal and informal social norms (see Lewis, 1969; Schotter, 1981; Aoki, 2001; Greif, 2006 for more sophisticated elaborations of this line of reasoning).

Some Types of Institutions

There are many different kinds of institutions. First, adopting the intuitive meaning of institutions as rules or constraints of behavior, it is useful to make the following distinctions. There are rules that regulate the personal life of human agents. These *personal* rules (e.g., the rule to go early to bed every night) resemble individual habits and individual routines. Some of these rules may be interpreted as attempts of individuals to commit or bind themselves. Personal rules may be motivated by individuals' long-term interests to achieve self-control. But they are not social institutions in the proper sense. Institutions require that routines and habitualizations are based on reciprocal typifications of interacting actors (Berger and

Luckmann, 1966: pp. 47–91). In contrast to personal rules, *social* rules affect social interactions; that is, recurrent situations of social interdependence. For example, it can be argued that social institutions typically regulate social dilemmas. Social dilemmas are situations where interdependent agents are faced with choices for which individual rationality does not yield a socially optimal outcome. The prisoner's dilemma and public good situations are cases in point. Furthermore, there are *formal* and *informal* institutions as special cases of social rules. Informal institutions do not rely on an external authority's monitoring and policing of the participants' behavior. These institutions include, for example, social norms of self-help among residents in rural communities (see Ellickson, 1991), or, to allude to an example from history, the community norms governing irrigation systems in villages of Tokugawa, Japan (Aoki, 2001, Chapter 2). Other informal institutions are conventions. Although conventions are defined as self-enforcing shared beliefs, they often become codified in formal rules (e.g., time standards or traffic rules). Formal institutions are generally created and arranged by agents who are able to rely on third parties for monitoring and enforcement. Among the most elaborate formal institutions in modern societies one should mention the law. There are also complex formal institutions regulating political committees in political systems and collective decisions in large capitalist firms. However, it is important to notice that formal rules are, in general, embedded in informal norms. Thus, formal institutional constraints are often supplemented by informal rules and vice versa.

Second, it is useful to point out the different levels of rules that can be relevant in institutional analysis (see Ostrom, 1990, Chapter 2). There is first the *constitutional* level. Constitutional rules define the most general context of the games agents are allowed to play. They determine the set of eligible actors and the principles used in crafting or changing more specific rules of the system. Constitutional rules are relevant not only in the arena of international and national politics but also in regional and local contexts. Second, there is the level of *collective choice*. Collective choice rules specify principles of policy making. They help to generate unique collective decisions. Third, there is the *operational* level. Operational rules help to implement the decisions of the higher levels. They determine day-to-day decisions; for example, decisions related to monitoring and sanctioning the participants.

Third, institutions may be classified by the domains or spheres of the society to which they belong and contribute. There are *economic* institutions regulating economic exchange; for example, property rights institutions. Other economic institutions include conventions with regard to media of exchange or the specific rules and constraints affecting economic behavior between and within firms (see Williamson, 1985). *Political* institutions provide basic rules and procedures to achieve collective decisions. The most important political institutions in contemporary societies are, of course, the constitutions of nation-states; for example, the constitution of the United States of America. There are also international political institutions. The European Union is constituted by a number of supranational institutions like, among others, the European Commission, which constrain national polities to a certain degree and provide a kind of federal framework for the set of participating countries. Besides these basic ground rules of international and national politics there are more specific institutions and laws dealing with the operation of the democratic system. Every human society has developed institutions shaping family life and kinship relations. Modern societies have created a differentiated system of educational institutions. There are also cultural and religious institutions of different kinds.

Explaining Institutions

The analysis of institutions has always been considered to be one of the most important tasks in social theory. For example, classic sociologist Emile Durkheim (1895) emphasized that sociology's subject was 'social facts,' in particular social institutions. Social facts are external or exogenous constraints to each individual. A desideratum of sociological analysis, according to Durkheim, is the discovery of the mechanisms, causes, and effects of institutions in the diverse spheres of societal life. There are multiple approaches to explain institutions and institutional change within the social sciences.

Effects of Institutions

A starting point of many explanations is the study of the effects or consequences of institutions. Not only functionalist theorizing in the proper sense but also many other approaches argue that institutions may have beneficial effects on different levels: For the involved agents institutions provide exoneration ('Entlastung' (A. Gehlen)) by reducing the complexity in the psychological process of everyday decision making (see Berger and Luckmann, 1966: pp. 53–54). Routines and habits yield lower costs of information and deciding.

Institutions regularize social life. Rule-oriented behavior reduces uncertainty and increases the predictability of others' actions in situations of social interdependence. The institutionalization of social norms in Parsons' sense is a key to the solution of the Hobbesian problem of order. In a 'state of nature' without an enforcing agency, mutual cooperation, for example, the recognition of private property rights, would be profitable, but there are strong incentives to defect from mutual agreements. The institutionalization of social norms of reciprocity and solidarity via their internalization into the actors' motivational systems would be, according to Parsons, a solution to the Hobbesian problem (Parsons, 1937). Thus, institutions and the institutionalization of appropriate social norms may foster cooperation and increase efficiency (in the Pareto sense of making agents better off without harming anyone in society).

Institutions such as exclusive private property rights with respect to economic resources are prone to enhance a society's aggregate welfare because they reduce transaction costs (North, 1990). If transaction costs within an economic system decrease, the economy will generally become more productive, provided the costs of creating and enforcing these institutions are not too high (see Eggertsson, 1990 for a survey of the literature). Many institutions, such as property rights and, more generally, the rule of law can be said to be part of a society's social capital

(Coleman, 1990, Chapter 12). In this sense, institutions are a productive asset because they enhance the efficiency, the welfare or, in other words, the well-being of most members of a society. Furthermore, they can have the properties of public or collective goods. That is, they are goods such that it is not feasible easily to exclude agents from their consumption if these goods are available to anyone. In other words, institutions with collective goods properties can be profitably 'consumed' by all those actors who wish to benefit from them, not only by those agents who contributed to the costs of their 'production.'

This public good characteristic of many institutions makes it clear that the potential beneficial effects of institutions cannot sufficiently explain the emergence and change of institutions. This is so because public goods create incentives to a free ride. If the formation and maintenance of an institution is costly, the amount of voluntary contributions to these costs will generally be too low, that is, suboptimal (Olson, 1971). At least for this reason, simple functionalist accounts of efficient institutions are incomplete.

Processes of Institutional Change

There are many different types of processes that are prone to generate or change social institutions. First, there is the extreme type of institutional change by conscious design. In particular, formal institutions such as legal norms are in many cases designed purposively. Parliamentary committees in modern democracies regularly propose such changes. However, many of these changes are anticipated, accompanied, or supplemented by changing informal institutions in the larger society. These informal rules often show a higher degree of inertia and change more incrementally.

Second, institutional change may be due to evolutionary forces of an 'invisible hand' (Adam Smith). In this case, the goal-oriented actions of a large number of actors may in the long rule unintentionally produce results that seem to be due to conscious planning by a central authority. But, in fact, the institution is a by-product of each individual's activity to locally adapt to its circumstances. Institutions of this kind are called 'spontaneous orders' (F.A. Hayek). It can be argued that many conventions have emerged as spontaneous orders (Sugden, 1986; Young, 1998) in the first place. Once adopted, they may be included in a cultural tradition and will be taught to children by their parents (e.g., table manners).

To explain institutions by invisible-hand processes (Ullmann-Margalit, 1978) is attractive because it may yield theoretical arguments with some 'depth.' Facts on the collective level of social institutions are by principles of purposive action and by a 'generating mechanism' (Boudon, 1979; Hedström, 2005). Obviously, most empirically observable institutions will not be explicable exclusively by one of these two extreme or ideal types of mechanisms but are probably complex combinations of different types of processes. However, the study of theoretical models representing some aspects of a complex reality in an idealized way may be understood as a theoretical 'thought experiment' (*Gedankenexperiment*). Such thought experiments enhance the clarity of theoretical arguments and provide an antidote against simplistic and empirically dubious 'conspiracy theories' of institutions (K.R. Popper), which argue that most social institutions are explicable in terms of the joint efforts of some group of powerful actors who want to foster their material interests.

Explaining Institutional Diversity

Given the functionalist account, which points out that institutions are or can be beneficial, one may ask whether in fact every institution is efficient. There is indeed some evidence on efficient rules. Wittman (1982) has investigated various microinstitutions like rules of thumb (like 'first come, first served') in certain road traffic situations in the United States and comes to the conclusion that only the most efficient rules will be used. Rules have evolved such that two types of costs are optimized, namely, costs associated with monitoring the rule and inappropriate incentives created by the rule. Similarly, Ellickson (1991) argues that rules that governed potential conflicts among whalers in the eighteenth century whaling industry spontaneously evolved such that they minimized transaction costs and deadweight losses. Rules were adapted to the particular circumstances such as the kind of whales and helped to improve efficiency with respect to defining and enforcing property rights about which ship is entitled to possess a whale in cases where several whalers competed about a catch. However, there is ample evidence on the emergence and persistence of prima facie inefficient institutions (see, for example, Edgerton, 1992). In certain rural areas of southern Italy, observers described the informal institutional pattern of an 'amoralist familism,' that is, family members follow the maxim: 'Maximize the material short-run advantage of the nuclear family. Assume that all others do likewise' (Banfield, 1958: p. 83). The set of shared beliefs implied by this rule obviously will generate a lack of cooperation and trustfulness in social and economic interactions with strangers (or actors outside the own nuclear family). There will be larger transaction costs and deadweight losses than those implied by alternative rules that are seemingly more prevalent in other Italian regions (Putnam, 1993). Moreover, economic historian North (1990: p. 6) points out that the "central puzzle of human history is to account for the widely divergent paths of historical change. How have societies diverged? What accounts for their widely disparate performance characteristics?" It seems safe to say, according to North, that market processes of competition did not weed out inferior institutions but that inefficient institutions have proved to be highly stable. Besides efficiency, distributional aspects of institutions are important. Some authors point out that there are two roughly different types of political institutions: inclusive and exclusive or extractive institutions (Olson, 1982; North et al., 2009; Acemoglu and Robinson, 2012). Extractive institutions concentrate political power in the hands of a small elite with little constraints or control of this power by other groups of society, whereas inclusive institutions tend to guarantee a significant degree of pluralism within the political system and the rule of law within society as a whole. Inclusive institutions foster inclusive economic institutions and therefore efficiency within the economy and economic prosperity of the society.

There are many different arguments that could explain the persistence of inefficient institutions:

1. As far as efficiency gains from institutional change are public or collective goods, there may be a lack of appropriate incentives to contribute to the costs (see Olson, 1971; Ostrom, 2005). In the management of self-governed local common pool resources like common fishing grounds or irrigation systems, some basic design principles must be followed to make possible viable institutions (Ostrom, 1990, Chapter 3): clearly defined boundaries, rules that are adapted to local conditions of the resource, effective decentralized monitoring and sanctioning, and some others. Given these conditions, users of a commons will have appropriate incentives to operate the resource in a sustainable manner. On the other hand, if some or most of these conditions are not met, inefficient institutions will emerge.
2. Inequality in bargaining power can have the effect of selecting institutions that primarily serve the interests of the more powerful agents or groups in a society. Thus, institutions need not foster the aggregate welfare of a society or efficiency (North, 1990, Chapter 6).
3. There are many recurrent interaction situations on different levels with multiple equilibria, for instance, situations resembling coordination games or iterated prisoner's dilemma games. In cases like these, the outcome may depend on specific boundary conditions; that is, historical circumstances and cultural traditions that are associated with different sets of shared beliefs. Thus, there is 'path dependence': Small differences in initial conditions and chance circumstances in structurally similar social interactions yield different paths of historical development and therefore different institutional outcomes (see North, 1990, Chapter 11; Young, 1998; Greif, 2006).
4. Limited rationality and incomplete information of human agents may be obstacles to attaining efficient institutions (North, 1990, Chapter 3). On the other hand, some results from variants of evolutionary game theory seem to demonstrate that stochastic elements and erroneous decision making within a population of boundedly rational agents can in the 'long run' help produce 'better' equilibria. The basic reason is that there are, in general, multiple equilibria that can be attained in the process of institutional change. Given that an inefficient, 'bad' equilibrium has been realized, stochastic shocks or individual mistakes in choosing a best reply to other agents' behavior may open the path to switch to a 'better' equilibrium. These equilibria, however, will in general not persist forever, even if they are efficient (Young, 1998; Aoki, 2001, Chapter 7).
5. Some social scientists, in particular in anthropology, suggest that institutions are generally inexplicable by functionalist or rationalist ideas. According to this approach, (cultural) institutions mainly serve 'symbolic' functions (Sahlins, 1976). Sociologists within the tradition of 'new institutionalism' argue that efficiency (whatever this means) is less relevant than 'legitimacy.' Institutional elements, for example, practices within organizations, will therefore be structurally similar to cultural norms that are common in other domains of society rather than based on the criterion of efficiency (see Powell and DiMaggio, 1991).

The Dynamics of Institutional Change

There are many different approaches with respect to the dynamics of change.

Research on the dynamics of the emergence of institutions has not yet provided a unified theoretical framework. There is, however, some agreement with respect to the criteria that an adequate approach should meet (see Aoki, 2001; Greif, 2006; North et al., 2009). Although it seems obvious that much change is due to exogenous factors (like technological change or other shocks), it is important to be able to explain institutional dynamics endogenously. This means that institutions are studied as self-enforcing systems of incentives in which the motivation is supplied endogenously: institutional elements like rules, conventions, or norms provide the information for each individual about shared beliefs. Given this information, an agent chooses the best reply – that is, to comply with the relevant regularity if the institution is consistent with an equilibrium in the Nash sense. The aggregate of individuals thus stabilizes and reinforces the institution. Second, stability and change must be studied within a single, unified theoretical framework. Thus institutional change has to be analyzed endogenously. There are many different analytic approaches. Classical game theory is arguably the most elegant and precise theoretical tool. However, there is some doubt about the empirical content and empirical accuracy. One problem is that classical game theory is indeterminate with respect to the outcome in situations with multiple equilibria. Game theory therefore seems to be basically a useful heuristic tool to clarify alternative explanatory mechanisms. Generally, the dynamics of institutional change will depend on initial conditions. That is, structurally similar social systems may develop qualitatively distinct institutions with considerable differences with regard to the degree of 'efficiency.' A particularly important aspect of initial conditions are 'cultural beliefs' in Greif's (2006, Chapter 9) sense. These beliefs are embedded into a society's culture and are a product of history. They are employed as equilibrium selection devices in those interaction situations with multiple equilibria. Therefore, different sets of cultural beliefs may yield different institutional outcomes (at least in the medium run). Greif (2006) illustrates this with the help of a comparison of the cultural beliefs in 'collectivist' and 'individualistic' societies, using the historical data on Maghribini and Genoese traders in the Middle Ages. An adequate theory should, in addition, point out the conditions that generate distinct cultural beliefs (and other equilibrium devices such as fairness norms) and the paths of an evolutionary transition from one equilibrium to another (possibly more efficient) equilibrium. In this respect, evolutionary approaches will be attractive.

Some ideas in this context are inspired by evolutionary game theory. Historically, the roots of evolutionary explanations of institutions are ideas from the tradition of the Scottish Moralists (in particular David Hume) and the Austrian School of Economics (Carl Menger and Friedrich A. von Hayek).

In constructing an evolutionary approach, one must keep in mind that there are important differences between biological and social evolution. Theories of social evolution must contain appropriate behavioral assumptions of adaptive behavior or learning processes. The evolutionary approach can be characterized by the following core ideas (see Young, 1998). Institutions are the products of interactions within large populations of actors over considerable periods of time. These agents are boundedly rational and act under conditions of limited information. This means that actors may fail to figure out responses to other people's actions that are optimal. However, *under appropriate circumstances,* the *evolutionary process* may in the long run (i.e., in the presence of stochastic shocks that correspond roughly with mutations in biological evolution) realize equilibrium outcomes such that efficient institutions persist. But this result may well be an exception rather than the rule. An evolutionary approach should, in principle, point out the conditions that generate distinct cultural beliefs (and other equilibrium devices such as fairness norms) and the paths of an evolutionary transition from one equilibrium to another (possibly more efficient) equilibrium. The evolutionary approach is a promising research program, but much further work is needed to fully understand and explain concrete cases of empirically observed institutions.

Abstract

This article introduces into the field of instructional design (ID) that is closely related to instructional technology, defined in terms of the application of scientific knowledge to the systematic design of learning systems. First, the relationship between instructional technology, design, and systems development will be described. Then we provide a brief historical overview to characterize relevant aspects of ID. Historically seen, the nine events of instruction as introduced by Gagné in the 1960s resulted in an abundance of models of systematic ID that were integrated in a comprehensive framework centering on five tasks: analysis, design, development, implantation, and evaluation (shortly called the ADDIE model). Along with the approaches of systematic ID some alternative approaches of learning and instruction emerged that were based on cognitive psychology and constructivism. These approaches will be discussed briefly before we describe, in some detail, present theories and applications of ID. Finally, we will discuss some challenges for future theory, research, and development within the realm of ID.

Instructional Design and Its Relation to Instructional Technology

The term instructional design (ID) refers to the systematic and professional planning and implementation of education or training. Considerations regarding planned instruction have been made at least as long as there have been institutions for instruction and training. The term ID itself appeared for the first time in the United States in the mid-twentieth century.

From its very beginning, ID was closely related to instructional technology, which is generally defined as the systematic application of theoretically and practically established knowledge to the development of learning systems, for which the name 'instructional systems development' (ISD) is also used. Often the relationships between ID, ISD, and instructional technology are expressed by the formula 'Instructional Technology = ID + ISD.' In a general sense, ID is defined as the entire process of instructional planning and implementation. However, the term ID is also used to denote a scientific discipline that refers to theory building and research on instruction and its implementation in various educational settings.

More specifically, the term ID is used in a variety of ways with different meanings:

1. The narrowest variant concerns only the planning of a particular instructional treatment.
2. The somewhat wider usage concerns both the planning and construction of that which is needed for instruction in various educational settings.
3. The even wider interpretation adds the implementation of the instructional system or program in a specific context as well as the evaluation of outcomes. The term ID is most often used according to this understanding and sometimes refers to instructional technology with the same broad meaning.
4. The widest interpretation adds to the previous meaning by including maintenance and management of the instructional system or program over an extended period of time; this includes conducting ongoing evaluations, planning, and developing upgrades as well as managing all of these processes in an organized and economical way. This broad interpretation of ID corresponds to the most comprehensive definition of instructional technology.

ID, under any of these interpretations, can refer to these education or training processes with regard to varying degrees of scope (unit of instruction, lesson, curriculum, program, system, etc.). At the *macro level*, ID concerns the instruction of complex curricula, programs, or systems that may cover months or even years of instruction; this is called *large-scale ID*, or, alternatively, curriculum construction and implementation. At the *meso level*, the object of ID is lessons that cover hours or weeks of instruction. The *micro level* concerns only short parts of a lesson, such as exercises or illustrative examples. The most frequent use of ID models refers to the meso level. However, the limits between the three levels are fluid and not always clearly defined.

Some authors tend to reduce ID to the mere planning of instruction as well as to restrict the term instructional technology to hardware and software, but these narrower interpretations do not meet the conditions of efficient instruction, because it has to take into account all relevant factors (e.g., learners, environmental factors) in a systematic way and in accordance with a systemic approach.

Today, education and instruction must increasingly accommodate a diverse set of students who need to learn complex cognitive skills and transfer them to a varying set of complex real-world settings and contexts. Accordingly, these new demands present a serious challenge to the field of ID. In particular, more powerful ID models are needed to deal with today's scientific and societal demands.

A Brief Historical Overview Characterizes Relevant Aspects of ID

The various essays about the short history of ID (e.g., Reiser, 1987) agree on the assumption that the systematic planning of instruction began in the 1920s. Usually, Tyler's (1922)

'Objectives for Learning' and Pressey's (1926) idea of teaching machines are considered as starting points. In accordance with Tyler's view on instruction, the 1930s were characterized by various attempts to establish a systematic planning of instruction, whereas the 1940s saw the rapid development of instructional media and training programs for the military. During these years, instruction as a special field of research and development was mainly stimulated by two general objectives:

1. Training as many learners as possible within a short period of time;
2. Using the most efficient available instructional means (e.g., media, such as written instructions and demonstration films, as well as practical exercises).

The Second World War introduced enormous training problems for the military in the United States. To address these problems, the 'Division of Visual Aids for War Training' of the 'US Office of Education' produced hundreds of films and training handbooks. Military training became an example for the successful connection of research and development to professional practice. Teams for instructional development started to see the use in including instructional designers as well as subject matter experts and a 'producer.' From that time on, the necessity for professional ID standards and professional ID practitioners has been recognized.

The next decade, the 1950s, was mainly characterized by the systematic application of basic learning principles of behaviorism to the development and implementation of programed instruction as well as to task analyses, with a particular emphasis on the adaption of instruction to individual learning conditions.

This educational movement culminated in the 'birth of ID' at the beginning of the 1960s, when Glaser (1966) introduced the term 'instructional design' into the literature and Gagné (1965) published *The Conditions of Learning*, which originally had a behavioristic orientation; later editions, however, provided an orientation on cognitive psychology (Gagné, 1985). In accordance with the idea of a hierarchy of learning processes, Gagné distinguished nine events of instruction that provided a fundamental basis for an instructional theory "to propose a rationally based relationship between instructional events, their effects on learning processes, and the learning outcomes that are produced as a result of these processes" (Gagné, 1985: p. 244). Based on the nine events of instruction, Gagné and Briggs (1979) contributed greatly to the emerging field of ID by answering three basic questions: (1) What is known about human learning that is relevant for ID? (2) How can knowledge about human learning be organized for concrete applications by designers of instruction? (3) What methods and procedures should be followed in applying knowledge of human learning to the design of instruction?

Gagné's theory, in combination with a systemic view (Salisbury, 1989), had unique effects on the development of various prescriptive ID models, such as the well-known model of Dick and Carey (1996) and various derivative models provided by Merrill (1983), Reigeluth (1983), Smith and Ragan (2004), and many others. These models agree on the assumption that learning can be classified in accordance with cognitive operations and processes that are similar by nature (i.e., internal conditions of learning) and can be facilitated by comparable instructional methods and strategies (i.e., external conditions of learning). However, the various models of ID initiated by Gagné do not provide a homogeneous class but rather focus on different components and strategies of ID. For example, Kaufman (e.g., 1988) focused on the particular role of needs assessment and strategic planning at different levels of education. In Kaufman's view, ID should not simply start with the formulation of instructional goals but rather with an analysis of the instructional objectives that are useful for the anticipated audience of particular learning environments. Needs analysis and strategic planning is still one of the most important areas of ID and ISD today.

Another important extension of ID models inspired by Gagné was the idea of automatizing the design of instruction and providing computer-based expert systems for this purpose (Tennyson, 1994). However, the idea of automating ID by means of expert systems can be considered as a failed project.

As a consequence of the rapid development of ID models, a major 'watershed' for the professionalization of instructional designers was reached in the United States in the middle of the 1970s. For the first time, instructional designers took precedence over subject matter experts as responsible contract partners for course development. In Europe this development was delayed.

Parallel to the emergence of ID models, but in contrast to their behaviorist orientation, some psychologists, such as Ausubel, Bruner, Cronbach, Glaser, Wittrock, and others, realized what is occasionally called the 'cognitive revolution' of psychology in the late 1960s (Bruner, 1990). To a great extent inspired by Piaget's epistemology, cognitive approaches of learning and instruction increasingly replaced the earlier behaviorist approaches (Shuell, 1986). This type of 'new' learning theories was called 'educational learning theory' (Bereiter, 1990). The introduction of educational learning theory has been associated with a strong tendency to investigate complex instructional matters.

This tendency as well as new societal and technological demands have challenged ID as a discipline, culminating in the constructivism–objectivism debate of the 1990s (Duffy and Cunningham, 1996). This debate can be considered as the expression of an essential uncertainty of ID theorists concerning the epistemological, psychological, and technological foundations of ID. This debate made essential contributions to the self-conception of ID by assimilating and advancing theories from cognitive psychology, systems theory, and communication technologies. Thus, recent additions to ID have been influenced by constructivism, situated cognition, e-learning approaches to distance education, and information theory. As a result of a Delphi study aiming at the identification of trends that may influence ID, Ritchie and Earnest (1999) point out that "with each iteration, we enhance our understanding of how to impact the performance of individuals and organizations" (p. 35) by means of designed instruction. So, for example, some approaches of ID have tried to integrate more systems thinking into ID. This includes (1) the view on instructional systems, subsystems, and their relationships to the environment; (2) the development of highly systematic, often linear or branched design procedures; and (3) more emphasis on systemic approaches of ID, which takes the

interrelationship between all relevant factors of instruction into account.

If we reconsider the various trends of ID during in the past two decades, we can state that theories and models of ID now come in different types and concern different worlds. In these different worlds, ideas about 'how to help people learn better' lead to different answers to the two basic questions of ID: "what to teach?" and "how to teach it?" (van Merriënboer et al., 2002). In general, the models of ID found in the literature can be classified into three 'generations' of ID. The first generation includes the development of procedural ID models (often illustrated as flowcharts) and is greatly influenced by Gagné and his disciples. The second generation of ID models contains approaches that can be understood as realizations of 'educational engineering' and aims at the automation of parts of the overall design process. The third generation, however, contains approaches which aim at the derivation of theoretically sound and research-based principles of the design of learning environments. The present applications of ID correspond to a large extent to generations (1) and (3).

Present Applications of ID

In accordance with the traditional procedural models of ID, present-day ID and ISD generally comprises the following subtasks:

- Performing a needs assessment,
- Identifying instructional goals,
- Analyzing goals into subgoals and identifying prerequisite knowledge,
- Defining what the learners have to learn to bridge the gap between prerequisite knowledge and subgoals,
- Developing criterion-referenced tests and/or other assessment measures,
- Developing instructional strategies,
- Developing materials and preparing media,
- Conducting formative evaluation, and
- Conducting summative evaluation (a final evaluation of the whole instructional procedure).

It should be noted that these are typical tasks found in many current ID models; variations among professional practitioner models still exist. Moreover, from a systemic point of view these subtasks are interrelated and are usually not performed in a linear way or only a single time; rather, the practice of ID is interactive and responsive to individual situations. However, in view of the vast amount of concurring ID and ISD models, a comprehensive framework – called ADDIE, an acronym for *A*nalysis, *D*esign, *D*evelopment, *I*mplementation, and *E*valuation – is widely used in ISD. Actually, ADDIE exists more as a label than as an ID model and its origins are not clear at all. It seems that the ADDIE model is an umbrella term referring to a family of procedural ID models which share a common underlying structure of ISD. Although there is no original and elaborated ADDIE model, most theorists in the field of ID agree that ADDIE is only an acronym that covers the major processes of the generic ISD process: *A*nalysis, *D*esign, *D*evelopment, *I*mplementation, and *E*valuation.

The phase of *analysis* contains, first of all, a needs analysis for different levels. Furthermore, this phase contains the analysis of objectives and performances as well as analyses of the addressees and the tasks and a cost–benefit analysis of the planned instruction. The *design* phase of ADDIE focuses on the design of a blueprint of the outcomes of instruction. Accordingly, the emphasis of this phase is on the design of a storyboard encompassing the entire structure of the instructional intervention or learning environment. At the center of design is the planning of instruction, and the necessary decisions refer to the orchestration of the external conditions for learning (e.g., methods of instruction, social interactions, media, and the organization of the environment).

The *development* phase of ADDIE contains the concrete realization of the decisions made in the design phase. More specifically, development concerns the production of the concrete learning material. The starting point of the development phase is a decision centered on the alternatives 'Buy it or make it.' In cases of doubt it is more efficient to work with preexisting material instead of producing it from scratch, and often it is more cost-effective to modify and adjust existing material to meet the requirements of a particular instructional situation.

Implementation contains the concrete realization of planned instruction in a real setting, for instance an online setting. Typically, the implementation of instruction occurs under controlled conditions and involves critical examination. This is often closely associated with a formative evaluation during the development phase. The *evaluation* phase of ADDIE refers to the test of whether the instruction was successful. The evaluation helps to measure the instructional impact on learners in terms of the predefined instructional objectives. Usually, a distinction is made between formative evaluation (i.e., a process-oriented evaluation of the development of instruction) and summative evaluation as an instrument of quality management. While it is perhaps the most popular model of ISD, the ADDIE model has some weaknesses, especially with regard to the development of multimedia-based instruction. For, example, ADDIE tends to be inefficient because it is not iterative. Furthermore, its strict sequence of steps tends to work well for static content but may be restrictive when one is dealing with learning outcomes that do not have a predetermined end state (e.g., complex problem solving). Another significant weakness is that there is no accommodation for dealing with faults or good ideas throughout the overall process of ADDIE. The designer must know all of the requirements before s/he develops the content to be learned. Probably the biggest weakness, however, is that ADDIE is nothing other than a mere extrapolation of former ID models that does not take into account new approaches of instructional psychology. As a consequence, the ADDIE model has been criticized as a "metaphor for the lack of clarity in the field of instructional design and technology" (Bichelmeyer, 2004).

These weaknesses have led to a number of spin-offs or variations, such as van Merriënboer's (1997) 4C/ID model or the Decision Oriented Instructional Design (DO-ID) from Niegemann et al. (2008). The four components of the 4C/ID model are authentic *learning tasks*, which are considered as the driving force of the intended learning processes, *supportive*

information (i.e., instructional assistance, coaching), *procedural information* (how to do things), and *part-task practices*. The DO-ID model of Niegemann et al. is an elaboration of ADDIE aiming at the design of multimedia.

For the time being, ADDIE can be considered as the culmination of the development of ID and ISD models in the tradition of Gagné and his disciples. However, in the 1990s alternative approaches emerged within the field of educational psychology. These new approaches aim at deriving theoretically sound, research-based principles for the design of learning environments for complex problem solving and guided discovery learning. They range from the design of learning tasks according to the Cognitive Load Theory (Chandler and Sweller, 1991; Paas et al., 2004) to comprehensive conceptions of instruction, such as anchored instruction, goal-based scenarios, and model-centered learning and instruction (see, for an overview, Seel and Dijkstra, 2004). The approaches of anchored instruction and goal-based scenarios can be considered historical and terminated events, whereas model-centered learning and instruction and the closely related approach of role-based design have developed into an increasingly prospering field of creative ID (Hanke et al., 2011; Hokanson and Miller, 2009; Seel, 2003).

ID approaches can be applied in all fields and situations that deal with education and training, including school settings, technical training, professional training, collaboration with human resource development professionals in industrial and professional organizations, higher education and university settings, as well as distance and lifelong learning situations – using all old and new kinds of media and telecommunications (see Bibliography). In short, ID has matured into a broad profession with many connections to other professions and activities, including personnel and project management.

It is especially noteworthy that the practice of ID often involves a variety of experts, such as text designers, media designers, software programmers, subject matter experts, and learning specialists. Such a team is obviously necessary when the development involves technology-based learning or instruction since the required skills and expertise are likely to be distributed among a variety of specialists. When ID teams are involved, it is critical to have recognized standards and an established methodology.

Challenges for Future Theory, Research, and Development

When we take into consideration the status quo of ID and technology we can state that there has been no significant change with regard to the general principles and methods of ID to date – and they were probably not necessary at all. Nevertheless, there are some important challenges in store for future theory, research, and development within the realm of ID:

- Dealing with integrated sets of learning goals for teaching complex skills and higher order skills. Such transferable skills are becoming more and more important in our society (cf van Merriënboer, 1997).
- An expert can broaden his or her competency by integrating the individual knowledge *and* the resources involved in obtaining, storing, and processing information into computerized tools. To take this into account we need to develop more powerful, integrated techniques for instructional and task analysis.
- Fostering the systematic design of collaborative learning/team training, of new technological developments in distance education, in particular web-based instruction.
- Dealing with highly heterogeneous target groups (differences in prior knowledge and skills, cultural diversity, older learners) and target groups with low motivation (e.g., 'adolescents at risk,' cf Attewell and Seel, 2003).
- Further development of effective forms of assessment. The need of assessment for efficient ID solutions is often underestimated.
- Automating ID processes using techniques of artificial intelligence. This can help to lower their cost, for example, by generating tasks for a given item format and content or producing instructional materials for a variety of products of the same type automatically.
- Last but not least, a better theoretical foundation of ID which takes into account the whole problem of providing *useful* knowledge for human beings in our world of nearly unlimited possibilities, in which we collect immense amounts of information from everywhere.

Ten years ago, an international consortium of researchers was organized by the International Center for Learning, Education, and Performance Systems (ICLEPS) of the Learning Systems Institute at Florida State with the aim of promoting new developments within the realm of ID. The cooperating partners and collaborators include numerous faculties and researchers from different universities around the world (e.g., the Open University of the Netherlands, the University of Freiburg (Germany), the University of Bergen (Norway), the University of Sydney, the University of Central Florida). ICLEPS has organized several workshops and meetings where studies were reported and discussed with an emphasis on integrated research for the development of human learning and performance systems. The stated mission of ICLEPS is to build on cognitive load theory, mental model development, and ID theory to investigate: (1) human cognition and social processes that mediate learning and performance; (2) factors that influence human performance; (3) conditions that promote practical and effective learning; (4) methods to assess individual and team progress; and (5) methods to evaluate programmatic change and diffusion of innovation. However, it seems that ICLEPS does not exist anymore. But this does not affect the future of ID.

Abstract

Instructional psychology is the study of learning processes in educational settings, and of the design of environments for eliciting those processes in view of attaining adaptive competence in subject-matter domains. A theory of learning from instruction involves five components: (1) description of desired end states of instruction; (2) description of initial states of learners prior to instruction; (3) explanation of transition processes from initial to desired states; (4) specification of instructional conditions that promote this transition; and (5) assessment of instructional effects. This article focuses on three components: adaptive competence as end state, constructive learning as lever for the transition to desired end states, and learning environments to promote transition.

Introduction

Instructional psychology is the study of the processes and outcomes of human learning in a variety of educational and instructional settings, and of the nature and the design of environments that are appropriate to elicit those learning processes aiming at the attainment of adaptive competence, i.e., the ability to apply meaningfully learned knowledge and skills flexibly and creatively in a variety of situations. The term 'instructional psychology' was introduced in 1969 by Gagné and Rohwer (1969) in the *Annual Review of Psychology* as title of their literature review of a field of inquiry indicated until then as 'educational psychology.' Today one can say that while educational psychology is somewhat broader in scope than instructional psychology – involving, for instance, psychological aspects of child rearing in the family – both terms cover largely the same domain of research, because most work has been done on studying knowledge and skill acquisition in instructional settings.

Since its earnest inception at the beginning of the twentieth century, the scientific study of learning has undergone major paradigmatic shifts (De Corte, 2010). In the behaviorist era, it was conceived of as response strengthening based on reinforcements. A fundamental change occurred in the 1950s with the advent of cognitive psychology: the focus on the central role of information processing by the learner led to the view of learning as the rather passive acquisition of knowledge. Stressing the active role of the learner as a sense maker resulted next in a new metaphor for learning as knowledge construction. In the 1980s, this constructivist view was amended by highlighting the important role of situations in which cognition and learning occur; from that development emerged the socio-constructivist conception of learning as participation and social negotiation. From an educational perspective, this currently constitutes the dominant view of learning. In this approach, the psychological processes evolving in the learner, on the one hand, and the social and situational aspects impacting learning, on the other hand, are considered to be reflexively related (Palincsar, 1998).

A comprehensive review of this extensive field of research is outside the scope of this article. Snow and Swanson (1992) have distinguished five essential components in a theory of learning from instruction: (1) description of desired end states or goals of instruction in a domain; (2) description of goal-relevant initial states of learners prior to instruction; (3) explanation of the transition processes from initial to desired states; (4) specification of instructional conditions that promote this transition; and (5) assessment of performance and instructional effects. This article will focus selectively on three of these components, namely desired end states, transition processes, and instructional conditions. For a more thorough overview of the field, especially from an Anglo-Saxon perspective, the reader is referred to the *Handbook of Educational Psychology. Second Edition* (Alexander and Winne, 2006), *The Cambridge Handbook of the Learning Sciences* (Sawyer, 2006), the *Handbook of Research on Learning and Instruction* (Mayer and Alexander, 2011), and *Educational Psychology: Concepts, Research and Challenges* (Rubie-Davies, 2011). To get a more comprehensive idea of European research, one can consult the periodicals *European Journal of Psychology of Education* (published since 1986), and *Learning and Instruction. The Journal of the European Association for Research on Learning and Instruction* (published since 1991).

Toward Adaptive Competence as Desired End State

Many scholars in the field of education now agree that the ultimate goal of learning and instruction in different subjects consists in acquiring adaptive competence, i.e., the ability to apply meaningfully learned knowledge and skills flexibly and creatively in different situations. This is opposed to routine expertise, i.e., being able to complete stereotype school tasks quickly and accurately without understanding.

Building adaptive competence in a domain requires the acquisition of several categories of cognitive, affective, and motivational components (De Corte, 2010):

1. a well-organized and flexibly accessible domain-specific knowledge base that constitutes the contents of a subject-matter domain;
2. heuristic methods, i.e., search strategies for problem analysis that increase the probability of finding the correct solution, because they induce a systematic approach to the task;

3. metaknowledge, involving knowledge about one's cognitive functioning (metacognitive knowledge) on the one hand, and knowledge about one's motivation and emotions relating to learning in a subject on the other hand;
4. self-regulatory skills, involving skills relating to regulating one's cognitive processes (metacognitive skills or cognitive self-regulation) on the one hand, and skills for regulating one's affective and motivational processes (motivational self-regulation) on the other hand;
5. affective components such as positive beliefs, attitudes, and emotions relating to oneself as a learner, and relating to subject-matter domains and learning and problem solving in those domains.

Prioritizing adaptive competence does not mean that routine expertise is unimportant. It is obvious that mastering certain skills routinely (e.g., basic operations in arithmetic, spelling, technical competencies) is crucial in view to efficient functioning in all kinds of situations. If certain aspects of solving a complex problem can be performed more or less mechanically, it creates room to focus on higher order cognitive activities that are needed to reach a solution.

In the early days of cognitive psychology, laboratory investigations using mainly knowledge-lean tasks showed the important role of general cognitive skills, such as heuristics, in skilled problem solving. But starting in the mid-1970s, expert–novice studies in rich content domains demonstrated the significant role of domain-specific knowledge in expert performance. This has stimulated in the last decades of the twentieth century the study of learning and teaching of school subjects that can be considered as one of the most significant achievements of instructional psychology of the past 25 years (Mayer and Alexander, 2011). One successful field of work in this respect is the research on conceptual change, i.e., the study of how concepts in subject-matter domains change with learning and development (Vosniadou, 2008). Yet research in the 1980s also evidenced that domain-specific knowledge could not fully account for human expertise, and showed that self-regulatory skills are a major determinant of successful learning and skilled thinking. The study of the cognitive, motivational, and emotional self-regulation of learning has since become a very productive area of inquiry (Zimmerman and Schunk, 2011). More or less in parallel, investigations also revealed the important influence on their learning processes and results of students' beliefs about knowledge and learning (Bendixen and Feucht, 2010). The view on adaptive competence conceived as the integrated acquisition of the different components described above, developed thus gradually over the past five decades.

Finally, adaptive competence as defined here implies the ability to transfer one's knowledge and skills to new learning tasks and problem situations, and in that perspective also the willingness to continually develop the breadth and depth of its components. As such, adaptive competence is crucial in view of lifelong learning. Transfer itself was always considered as an important goal of education, and therefore it is not surprising that since the early days of instructional psychology, it has repeatedly been, and still is, a major topic in research on learning and instruction. The available literature shows that transfer is a very complex phenomenon, that transfer effects do not occur spontaneously, and that they are even difficult to obtain deliberately (Alexander and Winne, 2006).

Constructive Learning as Lever for the Transition from Initial to the Desired End State

Due to the primary interest in unpacking the mental processes and knowledge structures underlying performance, the study of learning was rather unpopular in the early days of cognitive psychology. Toward the end of the twentieth century, however, this situation began to change. First, with the substantial progress made in the 1970s and 1980s in understanding knowledge structures, skills, and processes underlying expert performance, there reemerged an interest in the learning processes required to acquire such competence, and consequently in the instructional arrangements that can support this acquisition. Second, the rise of the socio-constructivist perspective that stresses the importance of context and especially social interaction stimulated interest in studying learning in the complex reality of classrooms. From this research a series of characteristics of effective and meaningful learning processes has emerged, which can be summarized in the following definition of learning: it is a constructive, cumulative, self-regulated, goal-directed, situated, collaborative, and individually different process of meaning construction and knowledge building. Only some of these characteristics can be briefly elaborated here (see De Corte, 2010 for a more detailed discussion).

Learning Is Constructive

Research has shown that learning is an effortful and mindful process, in which students actively construct knowledge and skills through reorganization of their already acquired mental structures in interaction with the environment. Some scholars – often inspired by the work of Piaget – take a radical position in this respect, claiming that all knowledge is a subjective and idiosyncratic cognitive construction. Others represent a more moderate point of view that allows for the possibility of mediating learning through appropriate guidance. Notwithstanding the large variety in theoretical perspectives along the radical–moderate dimension, the constructivist view certainly implies that acquiring knowledge and skills requires active cognitive processing from the learner.

Learning Is Self-Regulated

This feature refers to the metacognitive and metamotivational nature of effective learning, and is implied in the constructive perspective. Indeed, self-regulation means that students manage and monitor their own processes of knowledge building (Zimmerman and Schunk, 2011). Skilled self-regulation facilitates appropriate decision making during learning, as well as the monitoring of an ongoing learning process by providing one's own feedback and performance evaluations, and by keeping oneself concentrated and motivated. The more students become self-regulated, the more they assume agency over their learning; consequently they are less dependent on external, instructional support for performing those regulatory activities. As evidenced by Hattie's (2009) extensive meta-analyses, the largest effects on

students' learning are obtained when they display self-regulatory characteristics such as self-monitoring, self-evaluation, and self-teaching. Research also shows that students' motivational beliefs play an important role in self-regulation. This holds especially for their self-efficacy beliefs, i.e., beliefs about one's capabilities to learn and perform at a designated level (Bandura, 1986). An additional argument for promoting students' self-regulation of their learning derives from the finding that high levels of metacognition facilitate transfer: students having good metacognitive awareness and strategies are more able at using what they have learned to approach unfamiliar problems in multiple ways.

Learning Is Situated and Collaborative

The view referred to above that learning and cognition are situated emerged in the 1980s in reaction to the then prevailing mentalistic, information processing view of learning and thinking as highly individual and purely cognitive processes occurring in the head, and resulting in the construction of mental representations. In contrast, situativity theory – influenced by the work of Vygotsky – proposes a contextualized and social conception of learning and thinking: learning is enacted essentially in interaction with the social and cultural context and artifacts, and especially through participation in cultural activities and contexts. In other words, effective learning is not a purely 'solo' activity, but essentially a distributed one, i.e., the learning effort is distributed over the individual students, their partners in the learning environment, and the resources and (technological) tools that are available. Thus, this situated perspective strongly stresses the importance of collaboration in productive learning reflected in such activities as exchanging ideas, comparing solution strategies, and discussing arguments.

Although the literature provides fairly good support for this conception of learning (see, e.g., Bransford et al., 2006), the constructivist perspective has also come in for criticism: approaches based on constructivism rely excessively on discovery learning and provide minimal guidance to students, ignoring thereby the structure of human cognitive architecture and resulting in cognitive overload of working memory. These authors plea for a return to direct instruction. The critics are correct in concluding that pure discovery does not yield the best learning gains. But, they mistakenly equate constructive learning with discovery learning. Learning as an active, constructive, self-regulated process does not at all imply that students' construction of their knowledge and skills cannot and should not be guided and mediated through appropriate modeling, coaching, feedback, worked-out examples, and scaffolding by teachers, peers, and educational media. An extensive meta-analysis of the available research came to the conclusion that direct teaching is better than unassisted discovery, but guided, enhanced, or assisted discovery learning is superior to direct teaching (Alfieri et al., 2011).

Powerful Learning Environments to Promote Transition to the Desired End State

Powerful learning environments create the appropriate instructional conditions to evoke in students the learning processes that facilitate gradually the transition from their initial state toward increasing adaptive competence in a domain. Therefore, a challenging task for instructional psychology research consists of elaborating and validating a coherent framework of principles for the design of such powerful learning environments. Starting from the current knowledge and understanding of adaptive competence in a content domain (as described in Section Toward Adaptive Competence as Desired End State) and of the characteristics of effective acquisition processes (see Section Constructive Learning as Lever for the Transition from Initial to the Desired End State), but also based on observation of the practice of excellent teachers, this challenge has been addressed in a substantial number of design experiments. Such design-based research consist in the development and evaluation in real classrooms of complex and fundamentally new instructional interventions, guided by design principles that embody this present understanding of competence, of effective learning processes, and of successful teaching (see e.g., De Corte et al., 2003). Major examples of such orienting principles for the design of powerful learning environments are the following:

1. Learning environments should initiate and support constructive and self-regulated acquisition processes in all students, thus also in the more passive learners. However, as argued above, students' construction of knowledge can be mediated through appropriate guidance by teachers, peers, and educational media. In other words, the claim that productive learning requires good teaching still holds true. But, this first principle also implies that systematic interventions should gradually be removed, so that students progressively become agents of their own learning.
2. Complementary to the first principle, learning environments should allow for the flexible adaptation of instructional support, especially the balance between self-regulation and external regulation, to take into account individual differences among students in cognitive as well as in affective and motivational characteristics. Moreover, the crucial influence on learning of motivational factors points to the necessity of balancing instructional interventions and affective support.
3. Taking into account the situated and collaborative nature of effective learning, powerful learning environments should embed students' constructive acquisition processes as much as possible in (real life) contexts that have personal meaning for the learners, offer ample opportunities for distributed learning through social interaction and cooperation, and are representative of the tasks to which students will have to apply their knowledge and skills in the future. The progressive acquisition of adaptive competence will require extensive experience and practice with the different components involved in a large variety of situations.
4. Because domain-specific knowledge and domain-general heuristics and self-regulation skills play a complementary role in competent learning and problem solving, learning environments should create opportunities to acquire domain-general skills embedded in different subject-matter domains.
5. A variety of activating instructional methods should be used to initiate and support the intended learning processes. In

this respect, a whole array of methods is available that have been shown to foster students' learning: instruction based on modeling, feedback, scaffolding, worked examples, self-explanation, (computer-based) collaborative learning, inquiry, discussion, reflection, coaching and tutoring, visualizations, and computer simulations (see e.g., Mayer and Alexander, 2011)

Cognitive apprenticeship is a well-known model for the design of innovative learning environments that is largely in accordance with those principles (Collins et al., 1989). Although further research is needed to validate the design principles described above, a series of intervention studies in a variety of content domains that embody those guidelines to some degree have already reported supporting empirical evidence. Often these investigations also integrate educational technology, especially computer programs and multimedia systems, in their learning environments (Schauble and Glaser, 1996; De Corte et al., 2003).

Challenges

This selective, and thus incomplete review shows that over the past decades research in instructional psychology made substantial progress toward the elaboration of a theory of learning from instruction. Indeed, we now have a fairly good understanding of what adaptive competence in content domains involves, major characteristics of effective learning processes, and important principles for designing powerful learning environments to elicit and maintain those learning processes in students. But challenging issues need to be addressed in future inquiry of which the following are major examples. First, the expectations about the potential of research in instructional psychology for the improvement of schooling have not been fulfilled. Indeed, the substantial advances made in our understanding of learning and teaching have not resulted in a proportional innovation and improvement of classroom practices (De Corte, 2010). Bridging the gap between theory/research and practice constitutes thus a major joint priority task for educational researchers and professionals. Second, the high expectations about the contribution of information and communication technologies (ICT) for supporting and fostering student learning have until now not by far been met. Research is needed aiming at proving and realizing the incontestable potential of ICT for learning. Finally, a relatively new, challenging strand of research that emerged especially over the past decade is the interdisciplinary area of neuroscience and education. Currently still in its infancy, this field will in the future certainly contribute to the further deepening of our understanding of learning processes, for instance, by linking neural underpinnings to behavioral aspects of learning. However, in view of being relevant for education this domain of research must be conceived as a two-way cooperation with multiple reciprocal interactions between educational research and neuroscience (Bransford et al., 2006).

Abstract

The method of instrumental variables (IVs) is a general approach to the estimation of causal relations using observational data. This method can be used when standard regression estimates of the relation of interest are biased because of reverse causality, selection bias, measurement error, or the presence of unmeasured confounding effects. The central idea is to use a third, 'instrumental' variable to extract variation in the variable of interest that is unrelated to these problems, and to use this variation to estimate its causal effect on an outcome measure. This article describes IV estimators, discusses the conditions for a valid instrument, and describes some common pitfalls in the application of IV estimators.

The method of instrumental variables (IVs) is a general approach to the estimation of causal relations using observational data. This method can be used when standard regression estimates of the relation of interest are biased because of reverse causality, selection bias, measurement error, or the presence of unmeasured confounding effects. The central idea is to use a third, 'instrumental' variable to extract variation in the IV of interest that is unrelated to these problems, and to use this variation to estimate its causal effect on an outcome measure. This article describes IV estimators, discusses the conditions for a valid instrument, and describes some common pitfalls in the application of IV estimators.

The Method of IVs

Common Problems with Standard Regression Analysis of Observational Data

In many cases in the social and behavioral sciences, one is interested in a reliable estimate of the causal effect of one variable on another. For example, suppose a mayor is considering increasing the size of the police force; what is the effect of an additional police officer on the crime rate? Or, what is the effect of an additional year of schooling on future earnings? What will happen to economic growth if the central bank raises short-term interest rates by 1% point? What is the effect of a new medical procedure on health outcomes? These and many other questions require estimates that are causal, in the sense that they are externally valid and can be used to predict the effect of changes in policies or treatments, holding other things constant.

In theory, such causal effects could be estimated by a suitably designed randomized controlled experiment. Very often, however, as in the first three questions, such an experiment could be prohibitively expensive, could be unethical, and/or could have questionable external validity. Even when randomized controlled experiments are available, such as clinical trials of medical procedures, it is of interest to validate the experimental predictions using information on outcomes in the field. Thus, to address such questions empirically typically entails the use of nonexperimental, i.e., observational, data.

Unfortunately, standard regression analysis of observational data can fail to yield reliable estimates of causal effects for many reasons, four of which are particularly salient. First, there could be additional unmeasured effects, leading to 'omitted variable bias'; for example, the educational attainment of parents is correlated with that of their children, so if parents' education facilitates learning at home but is unobserved then the correlation between years of school and earnings could overstate the true, causal effect of school on earnings. Second, there might be reverse causality, or 'simultaneous equations' bias; for example, more police officers might reduce crime, but cities with higher crime rates might demand more police officers, so standard regression analysis of crime rates on the number of police confounds these two different effects. Third, there could be selection bias, in which those most likely to benefit from a treatment are also most likely to receive it; for example, because ambition is one reason for success both at school and in the labor market, the measured correlation between years of school and earnings could simply reflect the effect of unmeasured ambition. Fourth, standard regression estimates of the causal effect are biased if the regressor is measured with error (*see* Measurement Error Models).

IV Regression

IV regression provides a way to handle these problems. The main early application of IV methods was for estimating the parameters of a system of linear simultaneous equations, and this remains a good expositional framework. Let y_i denote the outcome variable of interest (say, log future earnings), let Y_i denote the r treatment variables (years of education), let X_i denote K_1 additional observed control variables, and let Z_i denote the K_2 IVs, where these are all observed for observations $i = 1,\ldots,N$. Also let β and γ be unknown parameter vectors, let Φ and $\prod$ be matrices of unknown parameters, and let β' denote the transpose of β. Suppose that these variables are linearly related as

$$y_i = \beta' Y_i + \gamma' X_i + u_i \qquad [1]$$

$$Y_i = \Phi X_i + \prod Z_i + V_i \qquad [2]$$

Where u_i and V_i are 'error terms' that represent additional unobserved effects, measurement error, etc. The coefficient of interest is β; in the schooling example, this is the percentage

change in future earnings caused by attending school for an additional year.

In this notation, the four problems listed in the preceding paragraph have a common implication, that the correlation between Y_i and u_i is nonzero, and in consequence the ordinary least squares (OLS) estimator of β will be biased and, in large samples, inconsistent. It is assumed that $\text{corr}(X_i, u_i) = 0$; at this level, this assumption can be made without loss of generality, for if this is suspected to be false for some element of X, then it should be listed instead in Y. In the terminology of simultaneous equations theory, y and Y are endogenous variables and X is exogenous.

The key idea of IV methods is that although Y is correlated with u, if Z is uncorrelated with u (that is, if Z is exogenous), then Z can be used to estimate β. Intuitively, part of the variation in Y is endogenous and part is exogenous; IV methods use Z to isolate exogenous variation in Y and thereby to estimate β. More formally, consider the simplest case, in which there is no X in eqns [1] or [2] and which Y and Z are single variables (i.e., $K_1 = 0$ and $r = K_2 = 1$). Then $\text{cov}(y, Z) = \beta\ \text{cov}(Y, Z) + \text{cov}(u, Z) = \beta\ \text{cov}(Y, Z)$. Thus, $\beta = \text{cov}(y, Z)/\text{cov}(Y, Z)$. This leads to the IV estimator, $\widehat{\beta}^{\text{IV}} = s_{yz}/s_{YZ}$, where s_{yZ} is the sample covariance between y and Z. Evidently, if these two sample covariances are consistent and if $\text{cov}(Y, Z) \neq 0$, then $\widehat{\beta}^{\text{IV}} \xrightarrow{\text{P}} \beta$. The availability of the instrument Z thus permits consistent estimation of β.

If more than r instruments are available, it makes sense to use the extrainstruments to improve precision. There are, however, many ways to do this, since each subset of r instruments will produce its own estimate of β.

The most common way to combine instruments is to use two-stage least squares (2SLS). In the first stage, eqn [2] is estimated by OLS, producing the predicted values $\widehat{Y}$. In the second stage, y is regressed against $\widehat{Y}$ and X, yielding the 2SLS estimator $\widehat{\beta}^{\text{2SLS}}$. With only one instrument, this reduces to $\widehat{\beta}^{\text{IV}}$ given above. Under Gaussian disturbances, this provides an asymptotically efficient method for weighting the various instruments that is easy to understand and to implement.

Conditions for Valid Instruments

The question of whether a candidate set of instruments can be used to estimate β is a special case of the more general problem of identification of parameters in multivariate econometric and statistical models. In the context of eqns [1] and [2], when there is a single Y, the requirements for instrument validity are simple. Then a potential instrument Z must satisfy two conditions: (1) Z is uncorrelated with u; and (2) the partial correlation between Y and Z, given X, is nonzero. The first condition states that the instrument is exogenous. The second condition is that the instrument is relevant. Together, these conditions permit using Z to isolate the exogenous variation in Y and thus to identify β. For example, when $r = K_2 = 1$ and there are no Xs, if Z satisfies the two conditions then β is identified by the moment condition derived above, $\beta = \text{cov}(y, Z)/\text{cov}(Y, Z)$.

When Y is a vector (i.e., $r > 1$), the exogeneity condition (1) remains but the relevance condition (2) is somewhat more complicated. For identification of the independent effects of each Y (all elements of β), a sufficient condition for instrument validity is that the covariance matrix of Z has full rank and that $\prod$ has full row rank. Clearly, a necessary condition for $\prod$ to have full row rank is that there are at least as many instruments as Ys ($K_2 \geq r$). The number of excess instruments, $K_2 - r$, is referred to as the degree of over identification of β.

When y is a vector, so that eqn [1] is itself a system of multiple equations, the conditions for identification become intricate (*see* Simultaneous Equation Estimation: Overview; Statistical Identification and Estimability). For a rigorous and complete treatment in the linear simultaneous equations framework, see Rothenberg (1971) and Hsiao (1983).

IV Estimators and Their Distributions

Linear Models

In addition to two-stage least squares, other estimators are available for IV estimation of a single equation that is linear in the unknown parameters. The leading alternative estimator is the so-called limited information maximum likelihood (LIML) estimator. The LIML estimator minimizes the Anderson–Rubin (1949) statistic,

$$F(\beta) = \frac{\tilde{y}'\left(\boldsymbol{M}_X - \boldsymbol{M}_{[X\,Z]}\right)\tilde{y}\Big/K_2}{\tilde{y}'\boldsymbol{M}_{[X\,Z]}\tilde{y}\Big/(N - K_1 - K_2)} \qquad [3]$$

$$\tilde{y} = (\tilde{y}_1 \ldots, \tilde{y}_N)', \quad \text{where } \tilde{y}_i = y_i - \beta' \text{Y}_i, \text{ and}$$
$$M_X = \mathbf{I} - \boldsymbol{X}(\boldsymbol{X}'\boldsymbol{X})^{-1}\boldsymbol{X}', \quad \text{where } \boldsymbol{X} = (\boldsymbol{X}_1, \ldots, \boldsymbol{X}_N)'$$

This can be solved analytically as an eigenvalue problem. Many other single-equation IV estimators have been proposed, but these are rarely used in empirical applications; see Hausman (1983) for expressions for the LIML estimator and for a discussion of other estimators.

Under standard assumptions (fixed numbers of regressors and instruments, validity of the instruments, convergence of sample moments to population counterparts, and the ability to apply the central limit theorem), the LIML and 2SLS estimators are asymptotically equivalent and have the same asymptotic normal distribution. That is, $\sqrt{\text{N}}(\widehat{\beta}^{\text{LIML}} - \beta)$ and $\sqrt{\text{N}}(\widehat{\beta}^{\text{2SLS}} - \beta)$ both have asymptotic normal distributions with the same covariance matrix. However, their finite sample distributions differ. There is a large literature on finite sample distributions of these estimators (*see* Simultaneous Equation Estimates (Exact and Approximate), Distribution of). Because these exact distributions depend on nuisance parameters, such as $\prod$, that are unknown and because few IV statistics are (exactly) pivotal, this literature generally does not provide approximations that are useful in empirical applications. However, some general guidelines do emerge from these studies. Perhaps the most important is that when there are many instruments and/or when $\prod$ is small in a suitable sense, LIML tends to exhibit less bias than 2SLS and LIML confidence intervals typically have better coverage rates than 2SLS.

These methods extend naturally to the case that y is a vector and eqn [1] is a system of equations. This entails imposing

restrictions on the coefficients in eqns [1] and [2] that are implied by the model, and then using the available instruments to estimate simultaneously all these coefficients with these restrictions imposed. The system analog of 2SLS is three-stage least squares, in which all the unknown coefficients are estimated simultaneously using an estimate of the variance–covariance matrix of u obtained from the 2SLS estimates. The system analog of LIML is full information maximum likelihood. For further discussion, *see* Simultaneous Equation Estimation: Overview; Simultaneous Equation Estimates (Exact and Approximate), Distribution of.

Nonlinear Models

Many details of the foregoing discussion hinged on the system being linear in the parameters and variables. In many settings, however, theory suggests models that are nonlinear rather than linear. A leading class of examples is consumption-based models of asset prices, in which the equations contain nonlinearities inherited from posited utility functions of representative agents. In such settings, eqn [1] is usefully extended and recast to incorporate these nonlinearities. Specifically, suppose that the model at hand implies,

$$E[h(y_i, Y_i, X_i, \theta)|X_i, Z_i] = 0 \qquad [4]$$

where as before y_i and Y_i are endogenous variables, X_i and Z_i are exogenous variables, and θ is a vector of parameters. For example, in the linear system eqns [1] and [2], eqn [4] is implied by $E(u_i|X_i, Z_i)$ upon setting $h(y_i, Y_i, X_i, \theta_0) = y_i - \beta' Y_i - \gamma' X_i$ and $\theta = (\beta, \gamma)$.

The orthogonality condition eqn [4] corresponds to the first condition for a valid instrument, that Z is exogenous. If in addition Z is relevant, then eqn [4] can be exploited to estimate the unknown parameters θ. The issue of relevance of Z is equivalent to whether θ is identified. The question of identification in nonlinear models is complex and little can be said about global identification at a general level, although conditions for local identification sometimes yield useful insights (*see* Statistical Identification and Estimability).

Given a model [4] and a set of instruments, in general a variety of estimators of θ are available. Estimation is typically undertaken by minimization of a quadratic form in $h(y_i, Y_i, X_i, \theta)$, times the instruments; 2SLS and LIML estimates obtain as special cases when h is linear. In practice, the choice of the weighting matrix in this quadratic form is important, and if there is serial correlation and/or heteroskedasticity this weighting matrix (and the standard errors) must be computed in a way that accounts for these complications. Such estimators are referred to as generalized method of moments (GMM) estimators. For discussions of identification and estimation in GMM, see Newey and McFadden (1994).

A Brief History of IV Methods

S. Wright (1925) and his father P. Wright (1928) introduced the estimator $\widehat{\beta}^{IV}$ (defined in Section IV Regression) and used it to estimate supply and demand elasticities for butter and flaxseed; this work, however, was neglected (see Goldberger, 1972). The development of IV methods in the 1940s stemmed from the attempts of early statisticians and econometricians to solve what appeared to be two different problems: the problem of measurement error in all the variables, and the problem of reverse causality arising in a system of simultaneous equations that describe the macroeconomy. The term 'instrumental variables' was first used in print by ReiersØ1 (1945), who developed IV estimation for the errors in problem of variables and extended work by Wald (1940) which, in retrospect, also can be seen as having introduced IV estimation. Concurrently, work by Haavelmo (1944) and the Cowles Commission emphasized likelihood-based methods of analyzing simultaneous equation systems, which implicitly (through identification conditions) entailed the use of IVs; Anderson and Rubin (1949) developed LIML as part of this research program.

An important breakthrough came with the development of 2SLS by Basmann (1957) and Theil (1958), which permitted computationally efficient estimation in single equations with multiple instruments. Sargan (1958) introduced IV estimation for multiple equation systems and Zellner and Theil (1962) developed three-stage least squares.

The extension of these methods to nonlinear models was undertaken by Amemiya (1974) (nonlinear 2 SLS) and by Jorgenson and Laffont (1974) (nonlinear three-stage least squares). The modern formulation of GMM estimation is due to Hansen (1982). GMM constitutes the dominant modern unifying framework for studying the issues of identification, estimation, and inference using IVs.

Potential Pitfalls

In practice, inference using IV estimates can be compromised because of failures of the model and/or failures of the asymptotic distribution theory to provide reliable approximations to the finite sample distribution. Much modern work on IV estimation entails finding ways to avoid, or at least to recognize, these pitfalls. This section discusses three specific potentially important pitfalls in linear IV estimation. These problems, as well as additional problems associated with estimation of standard errors, also arise in nonlinear GMM estimation, but their sources and solutions are less well understood in the general nonlinear setting.

Some Instruments Are Endogenous

If an instrument is endogenous then $\text{corr}(Z_i, u_i) \neq 0$, and reflection upon the derivation $\widehat{\beta}^{IV}$ and its probability limit in Section IV Regression reveals that $\widehat{\beta}^{IV}$ is no longer consistent for β. More generally, if at least one instrument is endogenous then the 2SLS and LIML estimators are inconsistent. If at least r instruments are exogenous, however, then it is possible to test the null hypothesis that all instruments are exogenous against the alternative that at least one (but no more than $K_2 - r$) is endogenous. In practice, a researcher might have at least r instruments that he or she firmly believes to be exogenous, but might have some additional instruments which are more questionable.

Testing the null that all the instruments are exogenous entails checking empirically the assumption that the instruments are uncorrelated with u_i. This can be done by regressing the IV residual (estimated by 2SLS or LIML) against Z. The R^2 of this regression should be zero; if NR^2 exceeds the desired $\chi^2_{K_2-r}$ critical value, the null hypothesis of joint exogeneity is rejected.

Although this statistic provides a useful diagnostic and rejection suggests that the full instrument list is (jointly) invalid, failure to reject is not necessarily reassuring since the maintained hypothesis is that at least r of the instruments are valid. Moreover, this test can only be implemented if β is overidentified ($K_2 > r$). The hypothesis that at least r instruments are exogenous is both essential and untestable, and thus must be contemplated carefully in IV applications.

Weak Instruments

The condition for instrument relevance states that Z and Y must have nonzero partial correlation (given X). In practice, this correlation, while arguably nonzero, is often small, a situation sometimes referred to as the problem of weak instruments. When the instruments are weak, the usual large sample approximations provide a misleading basis for inference: the 2SLS estimator in particular is biased toward the OLS estimator, and asymptotic LIML and 2SLS confidence regions have coverage rates that can differ substantially from the nominal asymptotic confidence level. When $r = 1$, an empirical measure of the strength of the instruments is the F-statistic testing the hypothesis $\Pi = 0$ in the first-stage regression eqn [2]. The risk of weak instruments is especially relevant when there are many instruments, for even if some instruments have a large partial correlation with Y, if there are many instruments quite a few of them could be weak so taken together this first-stage F-statistic could be small.

Although no single preferred way to handle weak instruments has yet emerged, one solution is to construct confidence intervals by inverting the Anderson–Rubin statistic eqn [3]. This is readily done because $F(\beta_0)$ has an asymptotic $\chi^2_{k_2}$ distribution under the joint null hypothesis that $\beta = \beta_0$ (a fixed vector) and $\text{corr}(X, u) = \text{corr}(Z, u) = 0$ (the instrument relevance condition is not needed for this result).

Heterogeneity of Treatment Effects in Microdata

Many modern applications of IV are to microdata sets with cross-sectional or panel data, that is, data sets where the observation units are individuals, firms, etc. An important consideration that arises in this context is the role of heterogeneity in interpreting what it is that IV methods measure. To make this concrete, consider a modification of eqns [1] and [2], where for simplicity it is assumed that $r = K_2 = 1$ and the only X is a constant. Suppose, however, that there is heterogeneity both in the responses of each individual to the 'treatment' Y and in the influence of the instrument on the level of treatment received. In equations, this can be written as,

$$Y_i = \mathbf{\Phi} + \prod_i Z_i + V_i \qquad [6]$$

where β_i and $\prod_i$ vary randomly across individuals. Suppose that the instrument is distributed independently of (u_i, V_i, β_i, $\prod_i$), and technical conditions ensuring convergence of sample moments hold. Then $\widehat{\beta}^{2SLS} \xrightarrow{p} E[\prod_i \beta_i]/E\prod_i$.

Evidently, with heterogeneity of this form 2SLS can be thought of as estimating $E[\prod_i \beta_i]/E\prod_i$, which differs from the usual estimand $\beta = E\beta_i$ if β_i and $\prod_i$ are correlated. For example, suppose that $\prod_i = 0$ for half the population, that $\prod_i = \prod$ (which is fixed) for the other half, and that the sample is drawn randomly. If β_i differs systematically across the two halves of the population, then 2SLS estimates the mean of β_i among that half for which $\prod_i = \prod$; this differs from the mean of β_i over the full population. More generally, 2SLS can be thought of as estimating a weighted average of the individual treatment effects, where the weights reflect the influence of Z_i on whether the individual receives the treatment. This has been referred to as the 'local average treatment effect'; see Angrist et al. (1996).

Where Do Valid Instruments Come from?

In practice the most difficult aspect of IV estimation is finding instruments that are both exogenous and relevant. There are two main approaches, which reflect two different perspectives on econometric and statistical modeling. The first approach is to use a priori theoretical reasoning to suggest instruments. This is most compelling if the model being estimated is itself derived from a formal theory. An example of this approach is the estimation of intertemporal consumption-based asset pricing models, mentioned in Section Nonlinear Models in which previously observed variables are, under the model, uncorrelated with certain future expectational errors. Thus previously observed variables can be used as instruments.

The second approach to constructing instruments, more commonly found in program evaluation studies (broadly defined), is to look for some exogenous source of variation in Y that either derives from true randomization or, in effect, from pseudorandomization. In randomized experiments in the social sciences, compliance with experimental protocol is usually unenforceable, so a subject's decision whether to take the treatment introduces selection bias; assignment to treatment, however, can be used as an instrument for receipt of treatment. In nonexperimental settings, this reasoning suggests looking for a variable that plays a role similar to random assignment in a randomized experiment. For example, McClellan et al. (1994) investigated the effect of the intensity of treatment (Y) on mortality after 4 years (y) using observational data on elderly Americans who suffered an acute myocardial infarction (heart attack). Standard regression analysis of these data would be subject to selection bias and omitted variables bias, the former because the decision to pursue an intensive treatment depends in part on the severity of the case, the latter because of additional unobserved health characteristics. To avoid these biases, they used as instruments the distance of the patient from hospitals with various degrees of experience treating heart attack patients, for example, the differential distance to a hospital with experience at cardiac catheterization.

If distance to such hospitals is distributed randomly across potential heart attack patients, then it is exogenous; if this distance is a factor in the decision whether to move the patient to the distant hospital for intensive treatment, then it is relevant. If both are plausibly true, then 2SLS provides an estimate of the average treatment effect for the marginal patients, where the marginal patients are those for whom the effect of distance on the decision to treat is most important.

From the humble start of estimating how much less butter people will buy if its price rises, IV methods have evolved into a general approach for estimating causal relations throughout the social and behavioral sciences. Because it requires valid and relevant instruments, IV regression is not always an option, and even if it is, the practitioner must be aware of its potential pitfalls. Still, when they can be applied, IV methods constitute perhaps our most powerful weapon against omitted variable bias, reverse causality, selection bias, and errors-in-variables in our efforts to estimate causal relations using observational data. For recent textbook treatments of IVs issues see Hayashi (2000: Chapters 3 and 4) and Ruud (2000: Chapters 20–22 and 26).

Abstract

The socially efficient allocation of risks in an economy of risk-averse agents is examined. This allows the potential social value of insurance to be measured. The reasons why most risks can be only partially insured are transaction costs, adverse selection, risqué moral, risk of fraud and limited liability, are then explored. The regulation of the insurance sector is also examined.

There is insurance when one party agrees to pay an indemnity to another party in the event of the occurrence of a predefined random event generating a damage for the latter. The most standard example is the insurance contract where the first party – the insurer – is compensated by being paid a premium by the second party, the policyholder. But many other contracts involve some forms of insurance. For example, in share-cropping contracts, the landlord agrees to reduce the rent of land in case of a bad crop. In many instances, employers agree to pay their employees more than the competitive wage in bad years. In cost-plus contracts, the buyer accepts to pay a larger price if the producer incurred an unexpected increase in cost. In the case of income taxes, the state partially insures the losses of taxpayers by reducing the tax payment when incomes are low.

The shifting of risk is of considerable importance for the functioning of our modern economies. Insurance is desirable for risk-averse agents as a risk-reduction device through the use of the law of large numbers. Moreover, insurance allows for disentangling investment decisions from risk-taking decisions. Without it, there would certainly not have been the experience of the historical economic growth of the twentieth century. Ford, Solvay, Rockefeller, and the others would not have taken the investment risks that they actually took without the possibility to share the risk with shareholders and insurers. Similarly, most consumers would not purchase new expensive cars or houses if they would not be able to insure them.

However, various informational problems (observation of the risk, solvency issues, of the prevention efforts and/or of the loss by the insurer) can make competitive insurance markets inefficient by not providing enough coverage at an acceptable price.

The Social Value of Insurance

There is an added value to insurance only because policyholders are risk-averse, that is they dislike zero-mean risk on wealth. Consider an agent facing a random loss X to their wealth. An insurance contract stipulates a premium P and an indemnity schedule I(.) that determines the indemnity I(X) for each possible loss X. There is full coverage if I(.) is the identity function. The actuarial value of the contract is the expected indemnity EI(X). The insurance premium is said to be actuarially fair if it is equal to the actuarial value of the contract, $P = EI(X)$. Suppose that it is the case. Then, the purchase of a full insurance contract at an actuarially fair premium has the effect of replacing a random loss X by its expectation $P = EX$. The private value of such a contract is equal to the risk premium attached to the initial risk by the policyholder. It is increasing with the policyholder's degree of risk aversion and with the riskiness of the loss. As a first approximation, the riskiness of the loss can be measured by its variance.

In order to determine the social value of insurance, the effect of the transfer of the risk on the insurer's welfare should also be measured. Consider an insurer selling n fair full insurance contracts to n policyholders, each of them bearing a random loss X_i, with $X_1, \ldots, X_n$ being identically and independently distributed. The common wisdom is that the insurer does not bear any risk in the aggregate, if it is able to sell enough such insurance contracts to cover independent risks, i.e., if n is large enough. This is not true, as explained by Samuelson (1963). It is a fallacious interpretation of the law of large numbers, which leads people to believe that accumulating several independent risks generates diversification. Indeed, the aggregate indemnity to be paid by the insurer is the sum of the X_i. Its riskiness measured by its variance equals $n\sigma^2$, where σ^2 is the variance of each individual risk X_i. If the insurer is risk-averse, the risk transfer is not Pareto-improving, since it makes the insurer worse off. The classical view of modern finance on this problem is to recognize that insurance companies are not owned by a single person, but rather by a large set of shareholders. If insurable losses are uncorrelated with financial markets returns, the riskiness of insurance companies has no adverse effect on shareholders. In such a situation, the risk transfer to insurance companies is Pareto improving, and the social value of insurance companies can be measured by the sum of the risk premia associated by policyholders to their random loss.

An alternative insurance scheme is to organize a mutual arrangement among the n risk-averse agents. Consider an arrangement in which the pool guarantees to each of its member a complete coverage of losses against an *ex-post* contribution equaling the average loss in the pool. In such a scheme, the random loss X_i is replaced by $(X_1 + \cdots + X_n)/n$, whose variance is $1/n$ the variance of X_i. In consequence, this mutual arrangement is Pareto-improving. At the limit, when n tends to infinity, individual risks are completely washed out by diversification.

Efficient Risk Sharing with Complete Markets

An important question is to characterize socially efficient allocations of risks in an economy where individuals may have

very different initial risk exposures and risk attitudes. Wilson (1968) solved this question when individuals are expected – utility maximizers. Any efficient allocation of risk must satisfy two conditions. The first one is often called the mutuality principle. It states each *ex-post* individual's consumption only depends upon the ex-post average wealth in the economy. This means that all members raise their consumption in good states, and reduce it in bad states. There is no loser in an improving environment. Notice that this condition is satisfied in the case of the mutual arrangement examined above. The intuition for the mutuality principle is the need for diversification: all individual risks must be gathered in the pool. The second characteristic of a socially efficient risk-sharing rule deals with the sharing of the aggregate risk in the pool. As suggested by the intuition, a socially efficient sharing of the aggregate risk is such that the risk borne by a member of the pool must be inversely proportional to their Arrow-Pratt degree of absolute risk aversion. At the limit, if there is a risk-neutral agent in the economy, this agent should bear all risks, i.e., he should insure everyone else in the economy.

Whether decentralized economies can allocate risks in an efficient way is another question that has been solved by the pioneering works of Arrow (1953), Debreu (1959), and Borch (1962). Suppose that the economic system is such that it is possible to freely insure against any bet, at fixed odds, any amount wished on the occurrence of any event, which will not affect the welfare of the insurers in any way. Markets are said to be complete in this case. Suppose also that there is no transaction cost on these markets, and no asymmetric information of any kind. The standard first theorem of welfare economics can then be applied to obtain that competition on these markets yields a Pareto-efficient allocation of risks in this economy. The competitive allocation must in particular satisfy the mutuality principle. At the competitive equilibrium, all households should sell their entire human and physical capital in exchange for a stake of the aggregate economy. A part of this story can be found in the Capital Asset Pricing Model in which all investors have the same composition of the portfolio of risky assets, the 'market portfolio.'

Townsend (1994) tested the mutuality principle in small rural villages in India. He did not reject the hypothesis of efficient risk sharing within each village. But he rejected the hypothesis of efficient risk sharing across villages. More generally, it is quite obvious that the mutuality principle does not hold in large economies. Some workers may see their income reduced in a booming economy. In case of a labor-saving macroeconomic shock, workers may lose against capital owners. Some classes of retirees may enjoy an increase in their pension benefit even when there is a recession. Some countries may be in recession in a growing world economy. Shiller (1993) recommends that new institutions be created to share these society's large economic risks that are currently inefficiently shared. The welfare impacts of imperfect risk sharing are likely to be very large. In the remainder of this article, the reasons for these market imperfections are examined.

Optimal Insurance with Transaction Costs

Insurance entails transaction costs. In many lines of casualty insurance, transaction costs may be as large as 30% of the premium. Consider an economy with a risk-neutral insurer and consumers with idiosyncratic risks X. Suppose that each euro of indemnity yields k euros of deadweight cost. In a competitive insurance market, the premium associated with insurance contract I(.) must be equal to $(1 + k)\mathrm{EI}(X)$. Mossin (1968) showed that the optimal insurance contract for the policyholder is no longer the full insurance contract. It is always optimal for him to retain part of the risk in order to reduce the insurance cost. This is because risk is a second-order effect relative to transaction costs.

Arrow (1965) examined the optimal form of the risk retention. There are various ways for policyholders to retain a share of the risk. The most standard is to accept a straight deductible, in which the indemnity is either zero, if the loss is less than the prespecified deductible, or the loss minus the deductible otherwise. Alternatively, the insurance contract can contain a coinsurance rule in which case, the indemnity is a prespecified percentage of the loss. Other clauses can be considered, as upper caps on indemnities, disappearing deductibles, etc. Arrow showed that the optimal insurance contract takes the form of a straight deductible. Any nondeductible insurance contract is dominated by a straight deductible contract with the same actuarial value, but yielding a smaller retained risk for the policyholder. Straight deductibles provide the best compromise between the willingness to cover the risk and the limitation of the insurance deadweight cost.

One can link transaction costs to undiversifiable risks. Obviously, many natural, environmental, or technological risks are in the class of large risks that are difficult to eliminate by using the mutuality principle. The insurer's risk-neutrality for these risks may be questioned. Insurance companies will not provide fair insurance premiums for them. Indeed, shareholders will not be able to diversify the risk associated to the dividends paid by insurance companies that cover these large risks. They will ask for a risk premium, which will increase the cost of capital of these companies. This cost will be passed on to policyholders through a larger premium rate for the component of individual risks that is systematic. It will induce them to retain part of their individual risk. In short, the fact that the risk is systematic induces insurance premiums to contain a positive loading that has an effect equivalent to a transaction cost. This is the logic behind larger deductibles for systematic risks.

Adverse Selection

Since the seminal paper by Rothschild and Stiglitz (1976), it is recognized that the fact that insurers face a heterogeneous population of consumers is a source of inefficiency on insurance markets. The classical model presented above allows for a heterogeneous population as long as the characteristics of the risk borne by each agent is common knowledge. For example, the fact that women are safer drivers than men is compatible with full insurance of every driver at the competitive equilibrium with a risk-neutral insurance industry. The premium rate for every category of risk will be fair, thereby inducing each individual to purchase full insurance at the optimum.

A problem arises when the population is heterogeneous, but the observable characteristics of the agents are not perfectly

correlated to the intensity of their risk. The adverse selection problem originates from the observation that if insurance companies calculate the premium rate on the basis of the average probability distribution in the population, the less risky agents will purchase less insurance than riskier agents. In the extreme case, the low-risk agent will find the premium rate too large with respect to their actual probability of loss. They will prefer not to insure their risk. Insurers will anticipate this reaction, and they will increase the premium rate to break even, only on the population of high-risk policyholders. The literature on adverse selection is devoted to characterizing an equilibrium. Insurers will use the fact that low-risk agents and high-risk agents behave differently in the face of a large set of insurance contracts. In particular, low-risk agents could credibly signal their type by selecting a contract with a large deductible, something that high-risk agents dislike.

The presence of high-risk agents generates a negative externality to lower-risk agents who are unable to find an insurance premium at an acceptable premium rate. To illustrate, this is probably why the proportion of households that purchase life insurance is so small, despite the potential severity of the risk. People have private information about their health status that cannot be observed by insurance companies. Then, only those with the lowest life expectancy purchase life insurance.

The standard policy recommendation for improving risk-sharing efficiency under an adverse selection problem is to make public all relevant information about risks. For example, insurers should be allowed to know whether the potential policyholder has some severe illness. They should also be allowed to use genetic testing. Obviously, redistributional reasons may go against such a policy recommendation if the state is not in a position to compensate poor high-risk agents.

Moral Hazard

The population of risks can be heterogeneous not only because agents bear intrinsically different risks, but also because they do not invest the same amount of their energy, wealth, or time in risk prevention. In particular, it has long been recognized that individuals who are better covered by insurance invest less in risk prevention, if the link between the premium rate and the size of these investments is weak. It will be the case, if insurers are not in a position to observe the investment in risk prevention by the policyholder. In that case, the premium rate is not sensitive to the effort made by the policyholder to prevent losses. Obviously, there will be an inverse relationship between risk prevention and insurance coverage; policyholders will not internalize the benefits of their efforts. The level of risk prevention will be inefficient. This is *ex ante* moral hazard, common to all principal-agent problems. Anticipating this low degree of prevention and the higher frequency of losses that it entails, insurers will raise their premium rate. Full insurance will not be optimal for agents. At the limit, no insurance can be an equilibrium. Holmstrom (1979) characterized the equilibrium insurance contract with *ex ante* moral hazard.

To illustrate, this is why it is not possible to insure against the absence of promotion on the workplace, about failure at school or university, about the lack of demand for a new product, or about divorce. To some extent, this is also why it is hard to insure against unemployment, or against environmental and technological risks.

The policy recommendation to fight against *ex ante* moral hazard is the enforcement of norms for risk prevention. This is the case for environmental risks in which ships transporting chemical products have to satisfy various safety requirements that are imposed by regulatory agencies. Automobile driving norms are also standard, as speed limits, alcohol-free driving, etc. Why these norms are mostly organized by a regulatory agency rather than by insurers is not completely clear. One reason is due to the combination of negative externalities and limited liability. If there is more than one principal supervising the implementation of norms, the information among the different principals should be pooled to save on monitoring costs. For example, auto insurers should be allowed to get the information about driver fines by the police.

Another policy recommendation is to allow insurers to discriminate prices among different policyholders that exercise various preventive efforts. Allowing for discrimination is a way to provide incentive to policyholders to invest in risk-reducing activities. In France again, insurers are not allowed to discriminate homeowner premium rates on the basis of natural risks such as earthquake, flood, and storms. The consequences are by now notorious: many households built their houses in areas that were secularly known to be flooded periodically.

Insurance Fraud

The classical model assumed that the size of the loss is observable. There are many instances in which this is at best a crude approximation of the real world. Contracts can be made contingent only upon observable events. The problem here is to give the good incentives to the policyholder to report their actual loss. The difficulty for insurers to verify claims is at the origin of why it is not possible to insure against loss of happiness, or against some forms of suffering that cannot be measured by physicians.

There exist other types of risk for which outcomes can be observed by the insurer only at a relatively high auditing cost. Townsend (1979), Mookherjee and P'ng (1989), and others analyzed the optimal risk-sharing scheme in this case. If there is no limit on the penalty that can be imposed to policyholders that do not declare the actual level of their loss, the first-best solution can be attained. Indeed, insurers should announce that they will audit claims with some probability p that is very low. If the policyholder made a fraudulent claim, an unbounded penalty ('death penalty') would be imposed on him. This is enough to give the incentive not to defraud the insurance contract, even if p is very small. In this case, the fact that there is costly claim verification is not detrimental to welfare, and the risk is insurable in full.

But there are several reasons to believe that an unbounded penalty in case of a fraudulent claim is not a realistic assumption: ethics, limited liability, risk of legal errors, etc. *Ex ante*, it is then Pareto-efficient to limit the size of the penalty. In order to report their loss correctly, the insurer will have to audit claims at a high frequency. This entails additional costs on the insurance contract. If the auditing cost is high, or if the frequency of audit necessary to give the good incentive for the

policyholder to reveal the truth is too high, consumers would be better off by not insuring the risk. Notice that another way to reduce the willingness to submit a fraudulent claim is to limit the indemnity. The maximal indemnity that is compatible with truth-telling is an increasing function of the penalty and of the probability of audit. Consumers would like to announce *ex ante* that they will not submit fraudulent claims *ex-post*. That would allow insurers to save the audit cost, thereby reducing the equilibrium premium rate, but the announcement is not credible.

Is *ex-post* moral hazard an important problem? It is often suggested that the cost of fraudulent claims may well amount up to 10% of premiums paid for such insurance lines as automobile insurance or homeowner insurance. This estimation is the cost of unjustified indemnities to policyholders, not the auditing cost to fight against fraud. This percentage is comparable to the rate of transaction costs, whose effects on insurability have been previously examined.

The policy recommendation is clear from the discussion above; one should impose a larger penalty on policyholders that have been convicted of a fraudulent claim. Several countries in Africa, and to a smaller extent in Europe, have been weak in this area, recognizing fraud as a 'national sport' that should be forgiven. By doing so, the legal system imposes a possibly large cost to society in terms of a loss of insurability. This weakness has been particularly clear for insurance lines where the indemnity payer does not have the good incentives to be tough on fraud. For example, one may question whether social security organizations are fighting fraudulent claims efficiently. This yields a general distrust of the system, which is detrimental to the unemployed themselves.

Limited Liability

An individual can cause damage to others, either in the course of his/her profession (medicine, surgery, house building, etc.) or because of other activities (e.g., driving a car). The same kind of external random effect occurs for firms. In most countries, the agent found liable for damage to others must indemnify them accordingly. This is done to force decision makers to internalize all costs generated by their choice. But indemnification is only possible up to the decision maker's financial capacity. Limited liability is a way to protect risk-takers against an excessive financial distress. But it has long been recognized that limited liability distorts the decision of the risk-taker in a way that is socially inefficient. The US Saving and Loans crisis is often explained by the fact that 'zombie' S and Ls adopted in the early 1980s, a very risky attitude in an attempt to 'bet for resurrection' after some blows were delivered to their portfolio of (real estate) assets. This is because limited liability gives the agent the equivalent of a free put option. Put it in simpler terms, under limited liability, an insolvent agent can only benefit from taking more risk, because he does not bear the burden of losses. Therefore, if the agent is risk-neutral, he will seek to maximize the expectation of a convex function of his wealth. As a result, he will systematically exhibit a risk-loving behavior, and adopt a very risky attitude. This is a kind of moral hazard problem. Risk aversion mitigates this result, but only for agents who are well capitalized.

The effect of limited liability of the policyholder on their demand for insurance is thus unambiguous; if he/she is risk-neutral, it is never optimal to cover a risk of loss, even in the most favorable case where the premium rate is fair. Insuring the risk would yield a sure reduction in wealth equaling the expected loss. Not insuring the risk would yield an expected reduction of wealth that is less than it, since the agent bears only part of the risk of loss. Another way of looking at this problem is that the insurance contract creates a 'deep pocket' where victims can find compensation for their losses. This kind of problem is particularly crucial when examining the demand for insurance by firms for catastrophic environmental risks. Limited liability on the part of the insurance also reduces the demand of insurance, since it makes the indemnity dependent on solvency.

Limited liability thus raises several important questions. How to organize compensation for those who bear the negative externalities? How to build an incentive-compatible mechanism that increases loss prevention by decision makers with limited liability? How to solve the market failure of liability insurance markets? How to force firms not to undercapitalize their subsidiaries, which are in charge of managing the riskiest part of the business? Two routes have been used. The first one is compulsory insurance. This solves the misallocation of risk in the economy and the organization of a system to compensate the victims. But, most of the time, compulsory insurance has been funded by a flat, nondiscriminatory, nonincentive-compatible insurance tariff. The policyholder's investment in loss prevention is not observed by the fund, either because it is difficult to get information on it, or because the fund did not organize an incentive-compatible system.

The second route has been to organize a 'deep pocket' for decision makers. For example, the hospital that employs an uninsured physician may be made liable in case of the physician's insolvency. Under the US Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), when a bank has been relatively closely involved in the monitoring of a firm's activities, it may be considered by the courts as liable for cleaning up the environmental damages generated by the insolvent firm. The objective of this strategy is to force risk-takers to internalize the full cost of potential losses; the hospital will reduce the income of the careless physician, and banks will increase the loan rate of riskier firms. If there is no asymmetric information between the principal (the hospital, the bank) and the agent (the physician, the firm), the agent will select the socially efficient level of care and insurance. There would then be no insurability problem. But, there is no reason to believe that the principal can monitor the agent at no cost. The CERCLA legislation, for example, introduces more asymmetric information on credit markets. Consequently, there will be more credit rationing, the cost of capital will be larger, and the structure of banking contracts for firms will be affected. Is insurability worth these costs?

Regulation of the Insurance Sector

Insurance markets are among the most heavily regulated ones around the world. In the Middle Ages, the Catholic Church was

reluctant to recognize insurance as an ethically acceptable activity. The French Revolution prohibited insurance companies in 1793. States have been very active to control insurance tariffs, in particular, in life insurance. They also imposed compulsory insurance. More recently, they established solvency rules similar to those of the banking sector.

There is a European tradition to use insurance for a redistributive purpose. Insurance implements wealth redistribution if the expected profit of the insurer depends upon the observable characteristics of the policyholders. The expected profit on the low-risk class of policyholders is used to cover the expected loss on the high risk class. This scheme is standard in unemployment, health, and disability insurance, but it can also be found in other insurance sectors like automobile (for young and old drivers), homeowner (for natural catastrophes), and life (for the prohibition of using health factors to price life insurance). However, the solidarity among different risk classes is difficult to organize with decentralized insurance markets without strong regulation. The absence of discrimination on the basis of policyholders' observable characteristics that are correlated with the risk introduces adverse selection. It also generates moral hazards if these characteristics can be affected by the preventive effort of the policyholder. In order to alleviate the adverse selection problem, regulators often impose compulsory insurance, as in social security systems. Pricing regulation is also necessary to react to the natural tendency of competitive markets to discriminate. Finally, insurers should be forced to supply coverage to all customers at the undiscriminating premium. Various reforms of the health insurance sector in OECD countries have been proposed to deal with the problems inherent in such heavy regulation.

There is a form of saving in an insurance contract from the policyholder's point of view. Indeed, the indemnity, if any, may be paid a long time after the premium. This is particularly true for life insurance. The lender, i.e., the policyholder, should check the solvency of the borrower–insurer. In perfect competitive markets, insurers facing a higher risk of insolvency should be penalized by collecting smaller premia, to compensate the risk borne by the policyholders. This is enough to provide good incentives for insurance companies to manage their financial reserves efficiently. However, policyholders may not be in a position to evaluate correctly the probability of failure of the insurers. This asymmetric information calls for centralized solvency regulation. It takes two forms. The first type of regulation is about solvency ratios, similar to those imposed on banks. The second type of regulation is about the kind of risks that can be taken by insurers on the investments they make with their financial reserves. Typically, there is an upper limit on the share of reserves invested in stocks and real estate. Many countries prohibit the use of derivative assets, in spite of their potential benefits for risk reduction. These constraints must be strong enough to fight against the moral hazard problem generated by asymmetric information and limited liability. It should not be too strong in order to allow for efficient asset liability management by insurers.

Abstract

Insurance and the law are interconnected. Legislation, court decisions, and regulations impact and influence the meaning of private and social insurance arrangements in society. While the law shapes and influences what insurance means in society, insurance also exerts a regulatory force over its subjects and acts as a form of governance beyond the state. Drawing from sociolegal scholars who study the gap between the law on the books and the law in action, this article explains the basic forms and functions of insurance in society and explores insurance's intertwined relationship with the law.

As Justice Black of the United States Supreme Court wrote in 1945: "Perhaps no modern commercial enterprise directly affects so many persons in all walks of life as does the insurance business. Insurance touches the home, the family, and the occupation or the business of almost every person in the United States" (United States v. South-Eastern Underwriters Association, 1945).

The law shapes and influences what insurance means, while the law is simultaneously influenced by insurance. Courts interpret the meaning of insurance policies, statutes establish what social insurance and other public sector insurance arrangements are permitted, and insurance regulations attempt to enforce state insurance laws, promulgate rules and regulations, and conduct hearings to resolve disputed matters pertaining to insurance. Private insurance arrangements in particular depend on a well-defined and robust contract law and a regulated market. While the law influences insurance, insurance also exerts a regulatory force over its subjects and acts as a form of governance beyond the state. Moreover, the presence of liability insurance often shapes how tort lawsuits are structured. Insurance is also an ideological construct that influences the relationship between law and regulation, such that much of society is governed through risk, both within the boundaries of insurance but even beyond insurance. Although ideas about what is insurable and what should be insurable vary over time and location, it is clear that risk and insurance impact so many aspects of society.

Drawing from sociolegal scholars who study the gap between the law on the books and the law in action, this article explains the basic forms and functions of insurance in society and explores the intertwined relationship of insurance and the law.

What Is Insurance?

Although there is not one formal definition of what insurance is (Kimball, 1992: 1; Abraham, 2013), insurance is generally thought of as a formal mechanism for sharing costs for misfortune or injurious experiences. Insurance deals with 'risk', that is, the chance that something can happen (often something negative). In the insurance field, risk is often conceptualized in two ways: (1) a person, property, or enterprise that is insured; and (2) the possibility that something can harm that person, property, or enterprise. Insurance essentially protects the persons or things insured against the possibility of harm.

Contemporary insurance arrangements are designed around a formal and organized scheme for the distribution of an economic loss over a large number of persons subject to the risk of a particular loss, with a goal of replacing the uncertain risk of loss with a predictable cost. The loss is often distributed by transferring the risk to an insurer (risk transfer). The loss is distributed in advance, often by charging a fixed premium or by charging an assessment after the event, or by some combination. For the insuring agreement to function well, the incidence of the loss should generally be reasonably predictable for some class of persons from which the participants will be drawn (risk pool), and therefore for any sufficiently large number of such participants taken at random (Abraham, 1986).

Because of the variation in the size and complexity of insurance, insurance can be characterized in multiple ways: (1) by line, which divides insurance into property and casualty insurance (fire, ocean, title, errors and omissions, and various forms of liability insurance) and personal insurance (life, accidental death or dismemberment, disability, and health insurance); (2) by interests protected, which distinguishes first-party insurance (the policyholder insures his or her own interest in a person's life or in property) and third-party insurance (liability insurance, which pays proceeds to a third party to whom an insured becomes liable); (3) by method of marketing, which distinguishes between group versus individual policies, and among insurance entities based on the methods used to sell policies (agents, brokers, etc.); and (4) by insurer organization, which acknowledges the various structures through which insurance entities operate (e.g., stock companies, mutual companies, reciprocal exchanges, Lloyd's associations, and various hospital and medical organizations) (Jerry and Richmond, 2012).

In general, legal scholars tend to divide the insurance law field into two subareas. One focuses on the law concerning the relationship between private insurance organizations and their insureds. This is most often developed from judicially articulated doctrines that regulate the relationship between an insurer and policyholder and is considered a part of contract law (although tort law and agency law principles and

some statutes and administrative regulations are sometimes important to this framework). The other realm of insurance law is largely a series of statutes enacted by state legislatures and administrative regulations developed by agencies that exist in most states. This is considered a part of the law of regulated industries (e.g., Baker, 2010; Jerry and Richmond, 2012; Cousy, 1999).

Insurance as Contract

Historically, insurance law has been considered derivative of contract law (Baker, 2008). Contemporary insurance institutions were derived from two distinct roots: (1) insurance as a mutual benefit protecting a fraternal group or (2) insurance as a commercial enterprise promoting trade and investment. Under either scenario, "insurance was a voluntary undertaking whose obligations were determined almost exclusively according to the rules governing the field of law that came to be known as the law of contracts" (Baker, 2008: 29).

By the mid-nineteenth century, courts in Europe and the United States recognized that insurance contracts were not traditional contracts, that is, voluntary agreements with terms that are negotiated between two parties with equal bargaining power. Rather, insurance policies are largely contracts of adhesion. Rarely do insurance companies and policyholders have equal bargaining power. Insurance companies typically use standard-form contacts with terms that are not subject to negotiation. Standard-form insurance policy provisions are often vague and drafted at a level of generality that leads to differing expectations about the scope of coverage within the policy. Moreover, most individuals do not have much knowledge about precisely what they are purchasing, especially because they often purchase insurance through intermediaries such as agents (who often offer minimal explanation of what the insurance policy provisions mean). On the other hand, insurance companies are often repeat players, wealthy, and the more sophisticated economic entity when dealing with a prospective insured. There is also not much variation in the market; with some exceptions (Schwarcz, 2011), insurance companies offer similar contract terms to consumers with similar profiles and needs. Moreover, insurance companies not only have more information, but better information concerning the meaning and value of the insurance policy than the person seeking to purchase insurance. Due to its gatekeeping function (see 'Insurance as Gatekeeper' later in the article), insurance is often not voluntary but a prerequisite to obtaining other privileges in society.

Although government regulation of insurance began in the United States during the latter half of the nineteenth century, the relationship between insurers and policyholders has remained largely within the domain of contract law. Courts and state regulations attempt to provide some protection to insureds, albeit with varying degrees of success. In particular, state regulations in the United States require premarket approval of some of the terms of insurance policies. Courts use the *contra proferentem* principle to try to protect insureds. Courts invoking this principle hold that ambiguities in a contract should be construed against the drafter. This interpretive principle is often used to supersede rather than interpret insurance policy language. Although regulatory agencies and courts can provide a formal check on the asymmetric relationship and require companies to reform the content of the standard form insurance policy, insurance companies often retain the contractual ability to modify insurance policy provisions going forward (to make policy provisions less ambiguous). By exercising this ability, companies can avoid judicial and regulatory scrutiny. Thus, contract law has and will continue to define the major aspects of the relationship between insurers and policyholders.

Insurance as Regulation

Insurance is also a form of regulation that affects many aspects of our lives. The state engages in the regulation of its citizenry by setting eligibility requirements and benefit levels for social insurance. Insurance companies establish the underwriting criteria, standards, and charge premiums. These mechanisms allow insurance companies to control who can or cannot obtain insurance. Through insurance policy terms and pricing, insurance companies also establish norms of conduct. Private insurance policies for life, health, and property often take the form of private legislation or regulation through exclusions and conditions. Thus, insurance is able to regulate even acts within the home or business, where traditionally individuals have been free from interference (O'Malley, 1991; Baker, 2010; Ben-Shahar and Logue, 2012). The following sections highlight two specific ways that insurance regulates law and society: (1) insurance as gatekeeper and (2) insurance as a specific form of tort regulation.

Insurance as Gatekeeper

Insurance serves a gatekeeping function in society because it is a prerequisite to other activity. Generally a person cannot register an automobile without automobile insurance, obtain a commercial business loan without business-owners' insurance, bid on a government contract without a surety bond, obtain practice privileges at hospitals without medical malpractice insurance, and sign a commercial lease without commercial property and liability insurance (Baker, 2010).

Home ownership in the United States quite clearly illustrates the gatekeeping function insurance plays. Home ownership is traditionally considered one of the fundamental features of the American economy. Thus, the availability of mortgages at a reasonable and affordable rate is often regarded as an important economic indicator. However, homeowners' insurance plays an important role in the availability of mortgages, because one cannot take out a mortgage without homeowners' insurance. In particular, obtaining homeowners' insurance is mandatory for standard mortgages and homeowners' insurers often use their own underwriting concerns that are independent from the screening procedures implemented by the lender (Squires, 1997).

Liability Insurance as Financier for the Tort System

Liability insurance acts as a form of tort regulation and in doing so, finances the civil litigation system. Tort law in action is often

shaped by the absence or presence of liability insurance. Over the past century, tort law has continually sought available sources of recovery and often creates and expands the liability of individuals and businesses that are likely to be covered by or have access to liability insurance (Abraham, 2008). As tort law expands, so does liability insurance. For example, medical liability insurance grew with medical liability and became so intertwined with it that occasional medical liability insurance crises are widely interpreted as medical liability crises (Baker, 2005a). Product liability doctrine has been facilitated by product liability insurance. Insurance companies responded by creating new forms of liability insurance to address the new liabilities when existing insurance was not available. Employment liability insurance rose as employment liability grew in the late nineteenth century. Moreover, state workers' compensation statutes enacted in the early twentieth century addressed the rising number of work-related accidents and the fact that the litigation system was unpredictable, expensive, filled with delays, and often led to small recoveries for people with work-related injuries. Workers' compensation laws allowed individuals suffering work-related injuries to receive compensation relatively quickly and without needing to obtain a lawyer and establish tort liability (Friedman and Ladinsky, 1967; Talesh, 2012). Even the US government took steps after the terrorist attack of 11 September 2001 to design a first-party liability insurance scheme, to compensate victims' families who otherwise would have had to use the tort system to seek relief. The compensation fund established by British Petroleum in response to the oil spill that occurred in the Gulf of Mexico in 2010 provides a more recent example of how insurance-based principles are used to preempt tort liability.

Because of consumer debt and the ability of bankruptcy courts to discharge civil liabilities, liability insurance is the primary asset on which plaintiffs can count when seeking to collect tort judgments. Without liability insurance, many underserved individuals who were innocently injured as the result of a tort by another person would not be compensated through civil litigation. Liability insurance in action means that when an injured victim brings a tort claim against a tortfeasor, it is the liability insurer that often defends the claim and, if necessary, pays the claim (Gross and Syverud, 1996). The presence of liability insurance consequently shapes how plaintiffs and defense lawyers litigate cases (Yeazell, 2001). A plaintiff lawyer's decision to represent an injured victim in a tort case is predicated not merely on proving the elements of a tort but on the defendant's ability to pay (Baker, 2005b). Liability insurance determines who can be sued, for how much, and for what wrongs. For individuals bringing tort-based lawsuits, "liability insurance is a de facto element of tort law, [and a] de facto cap on tort damages" (Baker, 2005b: 13). Even large corporations with significant assets often have liability insurance, but this relationship does not necessarily make litigation more efficient; large corporations involved in tort lawsuits often spend a significant amount of time convincing their own insurance companies to pay (Baker and Griffith, 2010).

In one of the early but influential studies of the gap between the law on the books and the law in action, Ross's (1970) study of automobile insurance adjustors in the late 1960s revealed how liability insurance led insurance claims administrators to focus on interpreting and implementing tort law by primarily managing aggregate costs rather than determining the individual fault of defendants:

> Adjustment of insurance claims compromises the legal mandate for individualized treatment with the need of a bureaucratic system for efficient processing of cases. This compromise can be observed at many points in the processes of investigation and evaluation. Investigation is vastly simplified, for instance, by presumptions as to liability based on the physical facts of the accident. Accidents are thus seldom individualized to an insurance adjuster or a claims attorney. Rather, they are rear-enders, red-light cases, stop sign cases, and the like and the placement of an accident into one of these categories ordinarily satisfies the requirements for investigation of liability….
>
> A large-scale society proceeds by routinizing and simplifying inherently complex and difficult procedures. This is how the work of the world is done. This is the law, as it is experienced by its clients rather than by its philosophers (Ross, 1970: 135).

Thus, under Ross's study, liability insurance is a bureaucratic claim processing mechanism that renders large amounts of tort law into a simple, manageable set of compensation rules and procedures. Although Ross focused on automobile claims, others have demonstrated how tort claiming is highly connected to liability insurance in a number of other tort subfields (Abraham, 2008; Abraham and Liebman, 1993; Baker, 2005a; Vidmar et al., 2005; Baker and Griffith, 2010).

Other forms of insurance also regulate tort law in action. When a statutory insurance scheme is in place, tort liability is often limited. Such statutory schemes have multiple effects: (1) they sometimes create a bar on certain types of tort claims; (2) they alter the manner in which tort claims are resolved by causing plaintiffs' lawyers to frame their claim in a manner that avoids being precluded from recovery; and (3) they lower the potential level of total recovery for a tort by making it more difficult to sue in tort when health, disability, or property insurance are covering an injury. Conversely, the existence of first-party insurance can sometimes (depending on the jurisdiction's collateral source rules) lead to a potentially higher tort recovery because collecting from the first-party insurance carrier shortly after the injury occurs can decrease the need or desire to settle early in the case, which allows litigants to pursue a more aggressive litigation strategy.

In some respects, legal insurance in Europe (and to a lesser extent in the United States) is an attempt to finance the litigation process even further by prospectively offering coverage for the risk and cost of a lawsuit. Legal insurance, legal cost insurance, or simply legal protection insurance is a form of voluntary private insurance that covers the costs of legal proceedings. With some variation, legal insurance in Europe covers all costs related to bringing or defending a claim, though not the claim itself. Although legal insurance covers claims arising out of contracts, social insurance, some family matters, and defense of criminal and misdemeanor cases (among others), "insurance for motoring and traffic accidents has been the main factor behind the expansion [of legal insurance]" (Raiser, 2001: 8639). Although less present in the United States, legal insurance is often reflected in two ways: (1) prepaid legal services offered by trade unions and professional groups to their members and (2) group legal

services plans, which cover workers in a particular branch and are financed primarily by the employers. These legal service plans allow workers and families greater access to legal counseling and, if necessary, legal support in court. Although neither the European nor the American markets are dominated by legal insurance, the existence of these insurance schemes reflects an awareness that litigation is often financed by insurance and provides a market for people to shift legal risk away from themselves.

Insurance as Governance

A series of empirical studies in the past two decades has also helped us understand how insurance institutions, forms, technologies, and visions (Ewald, 1991) act as a form of governance beyond the state (Ericson et al., 2003; Ericson and Doyle, 2004). Beginning with Heimer's (1985) inquiry into how insurers manage moral hazard in property and fidelity insurance relationships and continuing with Ericson et al.'s (2003) comprehensive research on the Canadian insurance industry, scholars have begun to understand how insurance is an institutional force with effects on individuals, organizations, and institutions inside and outside the insurance industry.

Ericson and his colleagues explain that insurance governs society through 'nine-interconnected dimensions' (Ericson et al., 2003). To begin, insurance simultaneously produces knowledge of risk, creates a scheme from which risks can be made objectively calculable, and develops a risk pool. In particular, these three dimensions of insurance classify everything into degrees of chance of harm and make everything calculable and consequently subject to commodification. Through actuarial techniques, concrete facts about objective risks are converted into probabilities and ultimately assigned a cost so that prices can be established. Actuarialism creates a risk pool, that is, a population that has a stake in the identified risks and the specific harms they entail. The risk pool transforms the population into a collective that seeks to minimize loss while also compensating those who suffer a loss. Turning to the fourth dimension, insurance does not protect against the particular event that causes harm to a member of the risk pool, but instead protects against a loss of capital that might result from that event. Their fifth and sixth dimensions identify the hybrid nature of insurance as both managerial and legal. Insurance manages risks in the population by using oversight, surveillance, and auditing while also making its risk pool subject to contract and ultimately adjudication. But insurance also assists the law in assigning liability to the party most capable of distributing the loss through insurance. Addressing the final three dimensions, these scholars explain how insurance's cultural, technological, and political functions impact and influence society in several important ways: "in providing a futures market in security, insurance offers a cultural framework for conceptions of time, destiny, providence, responsibility, economic utility, and justice." They also observe that "insurance is a social technology of justice. It bridges individual and social responsibility through distributive justice (collective sharing of loss) and restorative justice (financial indemnification)." For that reason, they contend, "insurance is … political, combining aspects of collective well-being and individual liberty in a state of perpetual tension" (Ericson et al., 2003: 6).

Scholars adopting an insurance-as-governance framework emphasize the way in which private insurers and governments exercise similar power in society and behave in a similar manner. In particular, the private insurance industry has many of the same goals as the state, including seeking forms of social security and solidarity by pooling risks. The private insurance industry provides technologies and social arrangements for allocating risk across pools of risk takers and provides for a sharing of the risks of misfortune through financial compensation of loss. It also attempts to establish preventative security arrangements that try to minimize harm and loss to its citizens. Thus, the private insurance industry governs through its powers to transfer and distribute risk, and it engages and involves the state only when necessary. The private insurance industry also uses many of the same methods as the state to achieve its goals such as surveillance, underwriting (sophisticated information systems for selecting risks), and claims (compensating loss). It also uses a substantial amount of private policing in the form of technologies, investigators, and inspectors to address fraud and achieve loss reduction and preventative security. Similar to the state, the private insurance industry is subject to many social, economic, and political forces (such as changes to the environment, economic globalization, terrorism, property and violent crime, and advances in medicine and health). The private insurance industry partners with the state to regulate insurance practices.

Consistent with the work of Ericson and his colleagues, there has been an effort in the past 20 years toward both theorizing and empirically exploring how the private insurance industry plays an active role in constructing the meaning of risk and responsibility in different segments of society. Notable governance-as-insurance studies include studying the role of property insurers in governing security in the home (O'Malley, 1991), highlighting the governance role of insurance companies in the motion picture industry in the United States (Hubbart, 1996–97), analyzing the rise of risk management approaches toward campus drinking (Simon, 1994), and examining the tort-settlement factoring industry in the United States (Scales, 2002). More recently, scholars are beginning to think about governance in the health insurance context. Hunter (2008) argues for using 'risk-centered governance' as the model for health law and policy. Hunter highlights how the debate in the United States over universal access to health insurance often links itself to the debate over the rise of actuarial medicine. She argues that the political attractiveness of 'risk' is subject to multiple interpretations and appropriations, including some that could mobilize pressure to use conceptions of risk in a more equitable manner (Hunter, 2008; see also Stone, 2002). Hoffman (2010) examined the Massachusetts mandatory health insurance experiment and identified how the fragmentation of health insurance risk pools that results from actuarial risk rating limits the ability of private insurance markets to carry out the social goal of redistributing health across society.

In sum, the private insurance industry acts as a system of governance through various forms of collaboration with state

governments: "sharing similar goals of security and solidarity through the pooling of risks; using similar techniques for governing at a distance; and collaborating in insurance regimes" (Ericson et al., 2003: 65). Insurance institutions are not just pooling and transferring risk, but instead actively shaping the world within which they operate. As these examples highlight, under a governance conception, insurance does not fit well within a public–private dichotomy. The relationship between insurers and policyholders falls somewhere in between the relationship between a public government and its citizens and a private relationship between two parties to a contract. However, private insurers are not agents of government; they are not subject to the rules, policies, and procedures that limit government discretion. Moreover, they are not required to afford policyholders constitutional protections (such as due process or equal protection) (Abraham, 2010). As the private insurance industry's governance role continues to grow, scholars going forward may want to consider standards for regulating the behavior of private insurers beyond those contained in administrative regulations, civil law doctrines, and contract law doctrines.

Insurance as a Tool for Increasing or Decreasing Social Stratification

Insurance in action often serves a social stratification function. Insurance law scholar Tom Baker argues that the "social stratification function of insurance is a more generalized way of thinking about the dynamic that makes insurance companies gatekeepers" (Baker, 2008: 10). As the prior sections highlight, the relationship between insurance and law in society is often mediated by insurance institutions, namely, insurance companies. Those individuals who cannot obtain insurance from insurance companies occupy a different social position than those who are able to obtain insurance. Moreover, people who have to pay more for insurance have fewer resources to spend on other things. To be clear, insurance companies are not the sole cause of such inequality. However, insurance companies do play an important role and in doing so, simultaneously construct and reflect the broader social conditions that lead to social stratification. In the context of first-party insurance, many life, health, and disability insurance companies have traditionally refused to provide coverage to people who have been treated for mental illness (Baker, 2002). Some insurance companies that are guided by an overzealous desire to insure 'good' risks sometimes 'cream-skim' and insure only 'good' risks and therefore decrease the likelihood of paying out on claims. This has the undesirable effect (from the standpoint of society) of leaving those most in need of insurance without being able to obtain coverage and increases the gap between 'haves' and 'have-nots.'

Conversely, insurance laws and regulatory schemes sometimes allow insurance to ameliorate social stratification and consequently serve the public interest (Talesh, 2012). In addition to liability insurance financing the civil litigation system, state laws require people to purchase automobile insurance and allow employers to opt into state-created workers' compensation insurance schemes. In doing so, insurance laws provide injured persons with insurance mechanisms through which to seek relief. Health insurance laws such as Medicaid and Medicare in the United States assist the poor and the elderly (and other groups) by increasing access to care to those who may not otherwise be able to purchase health insurance. Universal or socialized health care programs in Canada and some European countries (and more recently, the Affordable Care Act in the United States) also attempt to reduce social stratification. Though not perfect, insurance regulation, in addition to court decisions, attempts to ensure that insurance companies follow through on their promises, remain solvent, and avoid unfair business practices. Without insurance laws and regulations, policyholders could not possibly trust insurers to pay claims or remain solvent. As a system of risk spreading, transfer, and distribution, insurance can sometimes promote the public good and often allows individuals to seek compensation without needing to use a lawyer. In this way, insurance law acts in the public interest because it provides a collection mechanism for injured persons seeking compensation and relief for injuries (Talesh, 2012).

Governing through Risk beyond Insurance

Conceptions of insurance impact many social and legal relationships in society beyond the traditional insurance context. Insurance technologies and visions are used to govern risk outside of insurance institutions and risks that cannot or should not be governed by insurance. Baker and Simon refer to this concept as 'governing through risk,' the idea of using formal considerations about risk to direct organizational strategy and resources outside of (beyond) the traditional insurance context (Baker and Simon, 2002). There are numerous examples of governing through risk that draw on insurance technologies and visions but occur outside the traditional insurance context. To name a few, community policing models target high-risk areas (Ericson and Haggerty, 1997), social service agencies focus on at-risk children, environmental engineers conduct risk assessments of hazardous waste sites and other sources of environmental concern (Graham and Weiner, 1995), judges and policymakers debate tort and accident law in terms of allocation and spreading of risk (Calabresi, 1970), and financial analysts develop and structure portfolios based on a risk-reward ratio (Bernstein, 1992, 1996). Actuarial techniques are incorporated and mobilized by a range of institutions, from police departments to social service agencies to financial institutions. All these institutions rely on evaluating events based on probabilities and statistics and conceptions of risk that insurance has helped make possible (Ewald, 1986).

Risk-based principles drawn from insurance are increasingly a template through which to govern other relationships in society. There is at least one important difference, however, between insurance institutions using risk-based principles and noninsurance institutions using risk-based principles. Insurance institutions gather, pool, transfer, and spread risk and thereby eliminate or at least reduce the importance of those day-to-day concerns of people who are exposed to them. However, risks that are not subject to insurance

coverage, such as the examples I provided earlier, are not spread and eliminated in this manner, and therefore have significant consequences for the people exposed. A risk that occurs beyond insurance, therefore, is experienced in a much different manner than a risk that is insured. More recently, public and private insurance institutions are placing a greater emphasis on an individual's responsibility to embrace risk more directly. Scholars continue to engage in philosophical, theoretical, and normative debates concerning what distinguishes an insurable versus and uninsurable risk: "Because of the crucial role of insurance institutions in socializing risk and responsibility, studying risks beyond insurance opens a window on the limits of social responsibility and the role of ideas about individual responsibility in the shaping of insurance institutions and forms" (Baker and Simon, 2002: 12).

As this article highlights, insurance serves multiple functions in society. The forms and functions of insurance and conceptions of risk more broadly can have potentially positive and negative effects in society. Setting aside normative arguments concerning whether insurers' rising role in society is a good or bad thing, there is little doubt that insurance will continue to be intertwined and connected with the law and consequently impact society in multifaceted ways.

Insurgency

Abstract

Insurgency is the use of irregular tactics by a weaker foe seeking to impose military costs upon a stronger armed incumbent government or occupying power. Insurgencies have been ubiquitous in the twentieth century, with well over 200 new insurgencies emerging. Although insurgency has been a fairly popular method of conflict, it has not been particularly effective. The theory and practice of insurgency and counterinsurgency leaves many questions about why insurgency occurs, why it succeeds and fails, and how to respond to it. While key concepts and principles of insurgency and counterinsurgency brought to prominence in the mid-twentieth century remain largely visible in the contemporary world, scholarship must continue to evolve as new tactics and technologies revolutionize the nature of insurgency and political violence.

Insurgency Defined

Classical Definitions

Insurgency is as old as war. Ancient texts from the Bible to the histories of Tacitus record the use of irregular tactics by a weaker foe seeking to impose military costs upon a stronger armed incumbent government or occupying power. Indeed, as many have pointed out (Beckett, 2001; Nagl, 2002; O'Neill, 2005), incidences of insurgency and counterinsurgency (COIN) are historically more common than 'conventional' war. Yet traditionally such proto-insurgents were viewed as bandits or brigands, and the politicization of their activities was largely absent. Insurgency in its modern iteration has been defined by a particular series of events and thinkers, as well as by the rise of modern weapons and communications technology which have empowered small groups of insurgents to a level undreamed of in premodern times (Nagl, 2002).

Western thought on insurgency arose in response to the American War of Independence, in which American irregular units such as that commanded by Francis 'Swamp Fox' Marion played a significant part in keeping the largely loyalist southern states from returning to British control. The first European theoretical works on irregular war were written by veterans returning from service in the British Army during the American Revolution (Beckett, 2001: p 4). Revolutionary France's use shortly thereafter of the *levee en masse*, literally calling the entire French nation to arms eroded further the concept of the autonomy of war, and the Spanish nonconventional resistance to French occupying forces gave birth to the term *guerrilla* (literally 'small war'). Clausewitz soon after formulated his famous trinity of 'the people, the army, the state,' emphasizing the political nature of armed conflict and the insufficiency of merely defeating an enemy's armed forces in order to achieve victory.

All of these events shaped Western thought on insurgency. However, the concept's true birth comes in the thought and practice of Mao Tse-tung, whose 'revolutionary war' has served as modern insurgency's blueprint. Mao's primary insight is that in revolutionary war the primary battleground is the people themselves and the primary weapons are political. The revolutionary forces must "be like fish swimming in the water of the population" (quoted in Nagl, 2002: p. 28) – they must be both supported by and indistinguishable from the population at large. To that end Mao enjoined his guerrillas, even as they sought to intimidate the local population, to treat them with dignity and respect and to support local popular political issues. Temporary military defeat would be made irrelevant and could even benefit Mao's cause as long as the Communists maintained the support of the people.

Contemporary Uses

This essential focus on political legitimacy and the people defines contemporary insurgency. Modern insurgency's central characteristic is to undermine the people's belief in and consent to the incumbent government's rule. To this end the insurgency first utilizes political tools such as the distribution of propaganda to undermine the ideological basis for the government's rule and gain the people's support for their activities. Galula writes specifically of the importance of a cause, "The insurgent cannot seriously embark on an insurgency unless he has a well-grounded cause with which to attract supporters among the population" (Galula, 1964: p. 8). The effective dissemination of the insurgent's cause denies the incumbent regime ideological legitimacy.

In tandem with overt political activity, the insurgent engages in acts of violence, typically including terrorism and guerrilla warfare, to sap the government's will to continue the fight and to destroy the government's practical ability to govern and effectively deliver government services. Primarily operating from rural areas, areas of difficult terrain, or the 'urban jungle,' the insurgent slowly wears down its opponent and denies the government's claim to hold a monopoly of force. Insurgencies seek to gain control of territory but do not maintain a static control over a set territory, as such action would cause them to lose their 'fluidity' and put them in a disadvantageous position of conventional war in which the full force of their stronger opponent may be brought to bear. More important is control over the people. In an ideal insurgency, the continued use of violence against government forces and against those who do not cooperate with the insurgents further demonstrates to the people the impracticality of following government orders and eventually tips the balance of power in favor of the insurgency.

While this typical portrait of modern insurgency assumes that the insurgency's goal is regime change, contemporary scholarship has recognized a number of subcategories of

insurgency based on differing goals. O'Neill distinguishes between insurgencies seeking change in the political community (the state itself), the political system (the particular structures of the state), the authorities, and particular state policies (O'Neill, 2005). These varying types of insurgency are linked by their common application of insurgency's more basic indirect, population-focused, political-military strategy.

Insurgency Distinguished from Rebellion, Guerrilla Warfare, and Civil War

Insurgency has been distinguished in various ways from the more general civil conflict categories of rebellion (or revolution), guerilla warfare, and civil war. Galula contrasts insurgency from rebellion by its protracted nature. While revolution is an 'explosive upheaval,' an insurgency is "a protracted struggle conducted methodically, step by step, in order to attain specific intermediate objectives leading finally to the overthrow of the existing order" (Galula, 1964: p. 2). Thus while revolutions may involve long periods of planning, the event itself is characterized by sudden, unexpected social upheaval with widespread popular support. Insurgencies engage in a longer, protracted struggle in order to reach the ultimate goal of controlling the people.

Guerrilla warfare is typically an integral part of that longer, protracted struggle. However, guerrilla warfare in and of itself is merely a method which may be pursued by insurgents or state actors as a part of more traditional warfare. Many insurgencies rely not only on guerrilla tactics but also on clandestine, small-scale, armed operations, or terrorism, and indeed may be too weak to engage in guerrilla warfare at all until late in their development (Byman, 2008). And the contemporary, largely urban insurgencies in Iraq and Afghanistan often rely on a set of battlefield tactics foreign to traditional guerrilla warfare (Kilcullen, 2006).

Aspects of tactics and territory also distinguish insurgency from civil war. One of insurgency's defining characteristics is the insurgent's unwillingness to engage in a direct military conflict with his opponent. Thus while insurgencies seek to control territory, their control remains fluid. Civil war, however, is characterized by two subnational parties, each in control of a specific portion of territory, engaging in conventional conflict. As Galula says: "[Civil War] soon resembles an ordinary international war except that the opponents are fellow citizens" (Galula, 1964: p. 3). As insurgencies gain strength and firmer control over territory, their conflict may transform into a civil war – but this is by no means necessarily so.

The Onset of Insurgency

Researchers have spent decades identifying the causes of rebellion (Gurr, 1970; Goldstone, 1991; Fearon and Laitin, 2003). In macro explanations of substate violence onset, few scholars distinguish between insurgency and civil war. From 1900 to 2006, insurgency was a relatively common phenomenon. During that time period alone, 217 major insurgencies broke out across the globe. (This refers to insurgencies that involved at least 1000 battle deaths and sought to overthrow incumbent governments, achieve territorial secession, or drive out foreign occupation. All data referenced in this article come from the Nonviolent and Violent Campaigns and Outcomes Data Set, version 1.1 (Chenoweth, 2011).) In an average year, two new insurgencies set on worldwide.

As Figure 1 illustrates, the onset of new insurgencies steadily rose until 1980. Since that time, the patterns of onset have been a bit more erratic. Although there were fewer new insurgencies in the 1980s and early 2000s, a large wave of new insurgencies broke out in the 1990s owing largely to the breakup of the Soviet Union.

The vast literature tends to focus on two sets of causal processes – grievance and opportunity – to explain the onset of violent conflict. A scholarly consensus exists that both grievances and opportunities are necessary for insurgent mobilization, but neither alone is sufficient. For example, Jack Goldstone identifies three factors that lead to the onset of revolutions: financial instability, divisions among elites, and high mobilization potential (Goldstone, 1991). He argues

Figure 1 Number of insurgency onsets, 1900–2006.

that when these factors coexist in a society, they provide both the grievances (i.e., financial instability) and opportunities (elite divisions and high mobilization potential) that motivate people to seek the overthrow of their own governments. Figure 2 illustrates the typical grievance-opportunity approach.

Grievances

When scholars isolate the grievances that lead to violent conflict, they typically settle on perceived injustices, such as the unequal distribution of income, chronic poverty, or identity-based deprivations (Gurr, 1970; Collier and Rohner, 2008; Kaufman, 2006). Gurr (1970) finds that real economic grievances only arise when there are significant 'horizontal inequalities' (an uneven distribution of wealth), a finding corroborated by some (Cedermann et al., 2011; Do and Iyer, 2010; Nepal et al., 2011; Vadlamannati, 2011). When significant volumes of people are deprived of economic or political gains relative to others within the same society, a sense of shared grievance can develop against the wealthy or ruling class. Political grievances, such as the lack of political representation or channels for nonviolent expression, are also thought to be potential root causes of insurgency (Bohara et al., 2006; Carey, 2007; Gleditsch and Ruggeri, 2010; Goodwin, 2001; Joshi and Mason, 2008; Walter, 2004). And, in some cases, severe ethnic tensions may be associated with the onset of violent insurgency. Such tensions may arise when certain ethnic groups are excluded from economic and social benefits available to others within a given society (Cedermann et al., 2011; Wimmer et al., 2009). As many scholars point out, however, grievance alone is an insufficient explanation for the outbreak of conflict (Goldstone, 1991; Collier et al., 2009). Many people and nations experience considerable deprivations – both in absolute and relative terms – but do not experience the outbreak of insurgencies. This means that potential insurgents must perceive opportunities for mobilization as well.

Opportunities

According to opportunity-based approaches, violence emerges where the costs of using it are low and the probability of success is high (Fearon and Laitin, 2003; Collier et al., 2009; Hegre and Sambanis, 2006). In terms of domestic conditions, insurgency should be easiest where the state is incapable of repressing dissent because of a weak security apparatus or a lack of familiarity with local populations (Fearon and Laitin, 2003). Thies (2010) finds that primary commodities may have an indirect effect on the onset of armed conflict through the reduction of state capacity. We should also expect to see a higher probability of insurgency onset where weapons are easily accessible, such that large inflows of small arms could signal an impending insurgency. Fearon and Laitin (2003) find that mountainous terrain often facilitates insurgency in that insurgents are better able to take advantage of the terrain to evade government repression. New states, which may not have yet addressed prior grievances, established popular legitimacy, or incorporated armed militias, may also be more likely to experience insurgency (Fearon and Laitin, 2003). Opportunities for insurgency may persist in countries where civil war has recently occurred, draining the government's coercive capacity, allowing potential insurgents to access leftover weapons, and in some cases, providing former rebels with know-how and training (Zukerman Daly, 2012). Some scholars have also found that youth bulges – wherein a disproportionate percentage of the population is between the ages of 15 and 34 – are associated with the onset of civil conflict (Urdal, 2006). Large youth populations facilitate recruitment into armed groups, satisfying the need for willing participants (Goldstone, 1991).

Several external conditions may also increase perceived opportunities for insurgent mobilization. First, if an insurgency is occurring in a neighboring state, the easy availability of weapons, know-how, and additional fighters may convince would-be recruits to mobilize (Kathman, 2010; Gleditsch, 2007; Fearon and Laitin, 2003 Salehyan, 2007). Second, a foreign state's promise of weapons, cash, logistical support, intelligence, or sanctuary may also create opportunities – and incentives – for a new insurgency to set on (Chenoweth and Stephan, 2011; Record, 2006; Byman, 2005).

COIN: Theory and Practice

Intimately connected to the understanding of insurgency, and of primary concern to security studies scholars, and military practitioners, is the study of COIN. COIN theory may be approached from two basic perspectives or approaches. Nagl describes these approaches as the 'direct approach' and the 'indirect approach' (Nagl, 2002: p. 27–28).

The 'direct approach,' sometimes described as the 'French' school, is 'enemy' or 'kinetic' focused. It downplays the distinctive characteristics of insurgency and seeks to achieve victory through direct military action against insurgents. Frisch takes this perspective in his article on Israeli COIN strategy, arguing that the essential factor in preventing violence by Palestinian insurgent groups has been the military disruption of insurgent capabilities by the Israel Defense Forces (Frisch, 2006). Historical examples of this school of COIN in practice include the French COIN campaign in Algeria from 1954 to 1962 and the US 'search-and-destroy' campaign during the Vietnam War.

The 'indirect approach,' sometimes described as the 'British' school, focuses on defeating the insurgent through winning the 'hearts and minds' of the local populace. This is traditionally sought through good governance and effective security. Furthermore, this approach recognizes the importance of

Figure 2 Grievance-opportunity model of insurgency onset.

addressing the political grievances which gave rise to the insurgency. The counterinsurgent seeks to reconcile these political problems on his or her own terms, thus maintaining control while denying the insurgency its raison d'etre. This approach centers on the basic understanding of insurgency as a primary political activity. If people can be convinced both of the effective control and political legitimacy of the counterinsurgent, then the insurgent group will be unable to gain the material and ideological support necessary to continue its operations. Through increasing political irrelevance and waning numbers, the insurgency will ultimately be defeated.

The textbook example of this theory in practice is the British COIN campaign against the Malayan National Liberation Army in Malaya from 1948 to 1960. However, some scholars have argued that even in the case of Malaya, scholarship has overstated the importance of the British 'hearts and minds' campaign, and asserted that British victory in Malaya was assured primarily through the use of overwhelming manpower and continuous control of populated areas. The efforts to win 'hearts and minds' came only when the insurgency's main force had already been effectively defeated (Bennett, 2009; Hack, 2009).

While significant debate remains as to the efficacy of either of these approaches, the academic and military communities have largely embraced the 'British' school of COIN. The political focus on 'hearts and minds' is foremost in U.S. Army FM 3-24 'Counterinsurgency,' written by Generals David Petraeus and James F. Amos, which has served as the primary source of military doctrine for the American COIN campaigns in Iraq and Afghanistan (at least after 2005).

However, the U.S. COIN campaign in Iraq has given rise to a number of criticisms of this COIN strategy. Some have argued that the emphasis on good governance as a means of gaining legitimacy lacks relevance in communities where ethnic allegiances are the primary factor in determining legitimacy (Fitzsimmons, 2008). And COIN theorist David Kilcullen has argued that many contemporary Islamist insurgencies are best understood as theaters of operation aggregated into a larger 'global insurgency.' The insurgents in this global insurgency are motivated not by the traditional insurgent goal of regime change but by a larger vision of systemic change in the world order. This difference in central motive necessitates a radically different COIN response, including disaggregating local and regional grievances from the larger cause of global change (Kilcullen, 2005).

This dispute on the nature of insurgency illustrates one of the primary challenges of effective COIN: the necessity for clear understanding of the insurgency and accurate intelligence on its operations. As O'Neill states, "An effective counterinsurgency program depends on an accurate, substantive, and comprehensive profile of the adversary and the environmental context in which he operates" (O'Neill, 2005: p. 155). A correct understanding of the nature and context of the insurgency gives the incumbent government the necessary background to make correct policy prescriptions in its efforts to deny the insurgency political traction with the people. Many have argued convincingly for the importance of counterinsurgents understanding the culture, language, and local context of the people in which insurgents seek to operate (Kilcullen, 2006; Lyall, 2010). Clear understanding of insurgents' tactical preferences will also dictate varying COIN responses. Urban insurgency characterized by terrorism and the use of explosives necessitates a different response than rural insurgency characterized by guerrilla hit-and-run tactics. Because the insurgency avoids direct, open confrontation, it is essential that the counterinsurgent maintains excellent intelligence throughout a COIN campaign.

A second primary tactical challenge in COIN is distinguishing between insurgents and the people. Because insurgents deliberately conceal themselves within the population, COIN operations are often unable to differentiate between insurgents and civilians, leading to significant collateral damage. This has been particularly true in contemporary cases of insurgency in Iraq and Afghanistan, which have been primarily urban-based, in contrast to the primarily rural base of many 'classical' insurgencies (Kilcullen, 2006). While Lyall argues that in some circumstances indiscriminate violence against civilians may lead to a reduction in violence (Lyall, 2009) the general scholarly consensus is that collateral damage backfires on the counterinsurgent force by creating new grievances against the counterinsurgent and greater sympathy for the insurgent (Kocher et al., 2011; Condra and Shapiro, 2012). Condra and Shapiro in particular argue that civilians punish both insurgents and counterinsurgents for noncombatant casualties through the choice to share or withhold information regarding insurgents' activities from counterinsurgents, significantly hindering the counterinsurgents' ability to obtain effective intelligence on insurgents (Condra and Shapiro, 2012).

One tactical response to this dilemma proposed by Gompert is the use of a 'continuum of force' by COIN forces. Gompert argues that COIN operations may be conducted using a variety of nonlethal weapons such as 'directed sound and light' to separate insurgents from the larger population without causing civilian casualties (Gompert, 2009).

COIN theory and practice continues to evolve in response to the changing nature of modern insurgency. For instance, the rise of the Internet usage by insurgents has led to a reconsideration of the traditional idea of insurgent sanctuaries, and a subsequent emphasis on the importance of denying potential insurgents an 'online sanctuary' through which to build their cause. And doubtless COIN will continue to evolve in response to the United States' continuing 'live experiments' in COIN in Afghanistan and elsewhere around the world.

The Outcomes of Insurgencies

How often do insurgents win? Between 1900 and 2006, there was an average success rate of about 25% among insurgencies that involved at least 1000 battle deaths and sought to overthrow incumbent governments, achieve territorial secession, or drive out foreign occupation (**Figure 3**). Rates of insurgent victory peaked in the 1970s and 1980s, with close to 40% success. Secessionist insurgencies tend to be less successful than antigovernmental or anti-occupation campaigns.

Four major factors contribute to insurgent victory: resources, sanctuary, participation, and opponent response. First, insurgencies often have higher chances of success if they secure sponsorship by an outside state – particularly powerful states – that can help to finance and arm the group (Bob, 2005; Chenoweth and Stephan, 2011; Record, 2006). Second,

Figure 3 Percentage of victories among insurgencies, 1900–2006.

because insurgent groups are often vulnerable to repression by the state, sanctuary can prove an indispensible asset to many groups – particularly those with territorial goals (Salehyan, 2007). Third, participation is a crucial and oft-examined factor of success (Chenoweth and Stephan, 2011; Weinstein, 2007; DeNardo, 1985). Groups with large numbers are more flexible, more resilient to repression, and more capable of waging durable wars of attrition against their opponents. Fourth, opponent response is an important factor in explaining insurgent outcomes. States that are fragile or particularly incompetent in their response to the insurgency may be incapable of resisting a popular insurgency. Alternatively, selecting an inappropriate method of COIN may doom attempts to halt an insurgent campaign.

Although researchers have identified factors leading to the success and failure of insurgencies, they have often paid little attention to the considerable variation in insurgent success rates over time.

As Figure 4 demonstrates, whereas insurgency proved to be a relatively effective method of coercion during the mid-twentieth century with success rates far above the mean, it appeared far less fruitful pre-1930s and post-1990. What explains the variation in these rates of effectiveness over time?

Lyall and Wilson (2009) may have a partial answer. They argue that because of the mechanization of modern armies, counterinsurgent operations have become far less effective. Instead of using war fighting techniques that involve on-the-ground interactions with the civilian population consistent with the 'indirect approach' discussed above, contemporary armies tend to rely on technologies – aircraft, tanks, and the like – that emphasize the 'direct approach' and therefore provide very little population-centric information about the strategic environment. As such, intelligence – often argued to be the crucial element of COIN – is lacking. This may be true for the mid-twentieth century, where insurgent groups tended to enjoy far more victories than in recent years. Perhaps, modern

Figure 4 Change in insurgent victory rates, relative to mean, 1900–2006.

militaries have upgraded their understanding of COIN to include more population-centric COIN approaches.

A second potential explanation relates to the rise of nonviolent mass movements as alternatives to violent insurgencies. Recent research suggests that nonviolent resistance campaigns against dictatorships and foreign occupations tend to be more successful than violent insurgencies (Chenoweth and Stephan, 2011). This is especially true since the 1980s, when waves of nonviolent resistance swept through Eastern Europe and the Soviet Union. The decline in the effectiveness of violence may correspond to the rise of effectiveness of nonviolent resistance, suggesting that mass nonviolent movements may be displacing armed uprisings as the resistance method of choice in many contexts.

A third potential explanation – particularly for the decline in insurgent victories since 1990 – is the absence of willing sponsors of insurgent organizations. Although the United States and the Soviet Union avoided direct confrontation during the Cold War, both sides supported proxies throughout their so-called 'spheres of influence' in Latin America, Asia, Africa, Europe, and the Middle East. As such, the 1960s and 1970s saw the highest rate of state sponsorship of insurgencies, with nearly 55% of new insurgencies enjoying the sponsorship of a foreign power (compared with 38% over the entire 1900–2006 era). Incidentally, those insurgencies, which likely concluded in the following two decades, also tended to be the most successful against their opponent states.

Since the end of the Cold War, however, state sponsorship of insurgencies has returned to average rates – or fallen below them, depending on the decade. In the absence of great power rivalry, states may see sponsorship of insurgent groups as unnecessarily costly and provocative to their regional rivals.

Recent events in the Middle East and North Africa, however, may signal a return to the strategy of supporting insurgent movements. The NATO intervention in support of Libyan rebels against Muammar Qaddafi – and alleged Saudi, Qatari, and Turkish support of Syrian rebels against Bashar al Assad – reflects that states are still willing to take some risks in sponsoring violent nonstate actors who oppose their enemies. But, whether such strategies will continue to yield insurgent victories or longer-term strategic gains remains to be explored in future research.

Future Directions for Policy and Research

Important questions remain concerning the causes, outcomes, and responses to insurgency. With regard to the causes, the scholarly emphasis on broad structural conditions (i.e., grievance and opportunity) introduces two core problems: although extant research speaks to why people rebel, they do not answer precisely when or how people rebel. For example, such arguments fail to explain the specific causal mechanisms that drive insurgencies to break out at particular points in time. Populations may have a similar set of grievances and opportunities for long periods of time before the outbreak of insurgency. Why did an insurgency break out in Syria in 2011 but not in 2001 when the conditions of the Syrian population were largely similar?

Regarding the means of rebellion, both grievance and opportunity approaches assume that when potential insurgents do decide to mobilize, they do so using violence. A conventional wisdom persists that aggrieved groups respond – almost automatically – to structural conditions by arming themselves and using violence against the state. But in reality, campaigns of nonviolent resistance often occur before, during, and after insurgencies – and many nonviolent resistance campaigns pursue similar political objectives, and succeed, without an insurgency ever breaking out. Thus, grievances and opportunities may produce different patterns of resistance, which may or may not include insurgency. Further research is needed to clarify the conditions under which aggrieved parties with the capacity to undertake insurgency choose these various patterns of resistance.

With regard to the outcomes of insurgency, key questions also remain. First, researchers must better understand why insurgency is declining in its effectiveness over time. Although some plausible explanations are mentioned above, none of these has been systematically tested. Second, as mentioned above the post-Cold War dynamics of state sponsorship for insurgency, often an essential element for insurgent success, remain murky, with little research done into when, why, and how state actors choose to support violent resistance movements.

Finally, more questions remain about how states can better respond to insurgencies. In particular, most of the literature on the subject has been operational rather than scholarly in nature. Those who have developed 'best practices' in COIN have not yet ascertained whether those practices can easily apply in other cases. This critique particularly applies in the debate regarding collateral damage and the effect of civilian casualties on the success of insurgency. While several studies have proposed possible answers to this question based on specific COIN campaigns (Lyall, 2009; Condra and Shapiro, 2012; Kocher et al., 2011) there is little large-scale research.

Intimately related to this question is the question of how a counterinsurgent's actions may encourage or discourage participation in or support for insurgency. Is it more important – strategically and normatively – for the counterinsurgent to appeal to the peoples' 'hearts and minds' through good governance, political accommodation, and a light military touch? Or is it preferable to compel obedience and cooperation through a powerful kinetic-based COIN campaign?

More research is also needed into how COIN may be prosecuted effectively against insurgencies that do not fit the classical paradigm. What strategies and tactics are most effective against insurgencies that transcend the boundaries of the state, either through their character as the 'global insurgency' (Kilcullen, 2005; Jones and Smith, 2010) or through the use of new media and the shadowy sanctuary of cyberspace? While key concepts and principles of insurgency and COIN brought to prominence in the mid-twentieth century remain largely visible in the contemporary world, scholarship must continue to evolve as new tactics and technologies revolutionize the nature of insurgency and political violence.

Integrated Attachment Theory

Abstract

This article addresses core concepts of John Bowlby's attachment theory, underscoring the mechanism of primary drive reduction in the context of real-life events. We highlight Ainsworth's contribution to attachment theory and present her major advances such as the Strange Situation Procedure. We also review recent research including disorganized attachment, goal-corrected partnerships and attachment assessments through the life span, antecedents of attachment security/insecurity, the concept of maternal sensitivity, continuity and longitudinal correlates of attachment across the life span, attachment and genetics, and attachment-based interventions.

In one of his many influential papers, John Bowlby, father of the attachment theory, states: *Family doctors, priests and perceptive laymen have long been aware that there are few blows to the human spirit so great as the loss of someone near and dear. Traditional wisdom knows that we can be crushed by grief and die of a broken heart, and also that a jilted lover is apt to do things that are foolish or dangerous to himself and others. It knows, too, that neither love nor grief is felt for just any other human being but for one, or a few, particular and individual human beings. The core of what I am terming an affectional bond is the attraction that one individual has for another individual* (Bowlby, 1979: p. 75).

This statement is at the heart of attachment theory, which has since Bowlby's writing gained unprecedented research support and applied-clinical momentum in the field of human development. This wealth of research cannot be fully covered here. However, an interested reader may consult the 'Handbook of Attachment,' which has become the most authoritative reference (Cassidy and Shaver, 2008). Below we focus on what lies at the core of attachment theory, with attention to Bowlby and Ainsworth's perspective.

Bowlby's Trilogy of Attachment Theory

'Attachment,' 'separation,' and 'loss' are core terms of Bowlby's theory, and the names of his famous trilogy. Attachment theory addresses issues in human relationships and development, such as how children become attached to significant caring figures, what maintains close relationships, and how individuals react to separation or loss. Bowlby used simple albeit powerful terms and metaphors to express his ideas, and we continue to use them because their precision underscores forcefully the core tenets of attachment theory.

Attachment

According to attachment theory, all infants are innately biased to become attached to primary caregivers: *To say of a child that he … has an attachment to someone, means that he is strongly disposed to seek proximity to and contact with a specific figure, and to do so in certain situations, notably when he is frightened, tired or ill* (Bowlby, 1969: p. 371). The theory, which has been extensively validated cross-culturally (Van IJzendoorn and Sagi-Schwartz, 2008) emphasizes a 'specific figure' and 'certain situations,' mainly stressful. It is not a theory that refers to all human relations under all circumstances. Note however that the blooming of attachment theory and research in recent decades may have led to many misconceptions about how far Bowlby intended to go.

Primary vis-à-vis Secondary Drive Reduction

Perhaps because of his childhood experiences, and despite his background as a psychoanalyst, Bowlby strongly objected to the psychoanalytic consensus that viewed the infants' tendency to form relationships with their primary caregivers as 'secondary drive reduction.' Bowlby conceived such bonds as stemming from a primary and existential need, and viewed attachment as basic in and of itself: *Mother love in infancy is as important for mental health as are vitamins and proteins for physical health* (Bowlby, 1953: p. 182). In his seminal writing in *Child Care and the Growth of Love* (1953: p. 181), Bowlby asserted that *there is tolerance for conditions of bad mental hygiene in nurseries, institutions and hospitals… If it were found in the field of physical hygiene it would long since have led to public outcry*. He also opposed the view that the strong ties infants form with important adult figures evolves secondarily as an outcome of gratification with food or association with the mother's breast (Bowlby, 1940).

In an attempt to understand the implications of maternal deprivation, Bowlby was inspired by a broad spectrum of fields inside and outside psychoanalysis, including evolutionary biology, ethology, object relations theories, control systems theory, and cognitive and cross-cultural psychology. He was impressed by Spitz's (1946) writings on the effects of institutionalization on children, the work of Harlow (1961) on maternal caregiving and isolation from the mother in rhesus monkeys, the work of Lorenz (1935) on imprinting with geese, and of Hinde (1987) on ethology and social relationship, all of which express the ethological foundations of close relationships as independent primary motivational processes in survival terms (Bowlby, 1969, 1973, 1980; Duniec and Raz, 2011). Bowlby's personal background may also have contributed to his approach.

Edward John Mostyn Bowlby (1907–90) was born in London and grew up in an upper-middle-class family. Like many young children in similar families, he was cared for by

 http://dx.doi.org/10.1016/B978-0-08-097086-8.23198-X

nannies. Occasions on which he was allowed to spend time with his parents were strictly regulated: *My mother held the view that it was dangerous to spoil children… bids for her affection and attention were the opposite of what was required* (Bowlby in Byng-Hall, 1987: p. 19). Encouraged by his father, he went to study medicine at Cambridge. One of his tutors was enthusiastic about Freud's ideas, leading Bowlby to read psychological literature. Later he worked with maladjusted children and delinquent youths, and concurrently on his Ph.D., training in medicine, psychoanalysis, and psychiatry (Van Dijken, 1998).

Fantasies versus Real-Life Events

While training as a psychoanalyst, Bowlby found himself in continuous disagreement with his supervisor, Melanie Klein, and his ideas were not warmly welcomed by the psychoanalytic society in the UK. Klein emphasized the importance of early fantasies, marginalizing real-life events. She argued that the child's internal representations of the mother were strongly shaped by the child's drives, and were the ones that formed the child's psychic reality. Riviere, another one of Bowlby's psychoanalysis trainers, maintained that *[child] analysis has no concern with the real world … it is concerned simply and solely with the imaginings of the childish mind* (Riviere, 1927: pp. 376–377). At the end of World War II, Bowlby was appointed head of the Children's Department at the Tavistock Clinic. Most of the work there had a Kleinian orientation, insufficiently considering life events, and therefore not viewing family interaction patterns as important. For Bowlby, however, maternal deprivation, separation from attachment figures, and unresolved loss of close figures were key determinants of future adaptive difficulties. Consequently, he formed his own research unit to study the implications of mother–child separation.

Bowlby was greatly impressed by the work of social workers, especially Robertson (1953), who emphasized real-life events, the role of the family and environment as formative factors in the child's well-being and psychopathology. Together the two conducted naturalistic observations of hospitalized and institutionalized children who were separated from their parents. Bowlby went beyond infancy, suggesting that *all of us, from the cradle to the grave, are happiest when life is organized as a series of excursions, long or short, from the secure base provided by our attachment figures* (Bowlby, 1988: p. 62). One is reminded of present-day travelers, who immediately upon landing in a foreign country activate their mobile phones to call home for emotional refueling, to hear the calming voice of their loved ones; home is our secure base, which enables us to safely and comfortably explore new territories.

Separation

Bowlby (1944) suggested in '44 Juvenile Thieves: Their Characters and Home Life' that prolonged separation from the main caregiver in the first 5 years of life may render the young child susceptible to maladaptive behavior.

Again, his personal story may be related to his thoughts about separation. When Bowlby was 4 years old, his nanny left the household: *For a child to be looked after entirely by a loving nanny and then for her to leave when he is two or three, or even four or five, can be almost as tragic as a loss of a mother* (Bowlby, 1958: p. 7). At age 7, Bowlby was sent to a boarding school, and his connection with home consisted of letters and one to four visits per year. At age 14 he entered the Royal Naval College at Dartmouth. He was probably unhappy in these settings and as an adult spoke strongly against them (Van Dijken, 1998).

Robertson and his famous documentary filmed observation 'A two-year-old goes to the hospital' (Bowlby and Robertson, 1952) was of formative significance for Bowlby, who contended that when a child is separated from an attachment figure unwillingly, he shows distress. Distress is likely to intensify if the child is exposed to an unfamiliar environment and the care is provided by a stranger. Bowlby described the child's behavior under such circumstances as progressing through a three-stage process: *protest* – expressing separation anxiety, the child uses his or her sensorimotor repertoire to draw his or her caregiver back; *despair* – after protesting, the child realizes that he or she is not able to regain his or her caregiver but remains preoccupied with the caregiver and alert to any signs of return (behavior signifying grief and mourning); and *detachment* – after a while, the child seems to lose interest in the caregiver and becomes detached from his or her as a defense strategy. However, the child does not remain detached indefinitely. After reuniting with his or her caregiver, his or her attachment system reactivates. After experiencing such a process, the child insists on staying close to his or her attachment figure, exhibiting elevated anxiety when suspecting that the caregiver might leave again.

For many years, pediatric wards worldwide did not allow parents to stay with their hospitalized children. The focus was on "medical intervention" per se, ignoring the children's other basic needs, such as attachment needs. Such (mal)practice and its possible ill effects on recovery from the illness have been studied extensively in recent decades, but Bowlby was a pioneer to express these ideas as early as the 1950s.

Loss and Grief

Under prolonged separation, as in the case in loss, grief and mourning take place with despair as the most pronounced behavioral marker. Bowlby's view is consistent with Parkes (2009) who emphasized the important function of working through the loss with successful resolution. Unlike the psychoanalytic tradition, Bowlby viewed depressive responses following the loss of an attachment figure not as outcome of unconscious fantasies but as a reaction to real-life events, namely, death, abandonment, or prolonged separation. According to Bowlby, children separated permanently from their attachment figures, without trustful substitutes – as in the case of many maltreated children placed in group care settings, or of abandoned and orphaned children in institutions – may lack the capacity to love because of an absence of opportunities in their early years to form close ties with an attachment figure.

Ainsworth and Growing Points in Attachment Theory

A fortunate coincidence, an advertisement in the *Times* magazine, connected Bowlby with Mary Salter Ainsworth who became his most influential colleague: Ainsworth (1913–99), a Canadian psychologist, wrote a doctoral dissertation

inspired by Blatz's 'security theory.' According to this theory, during early childhood, parental support of the child's explorations will help him form 'independent security': *where family security is lacking, the individual is handicapped by the lack of a secure base from which to work* (Salter, 1940: p. 45).

When Ainsworth joined Bowlby's team, she became impressed by Robertson's naturalistic observations as a way of recording children's behavior and decided to adopt the method when undertaking her own research. Her husband's anthropological research took Ainsworth to Uganda, where she began documenting normative developmental changes during infancy and individual differences in patterns of mother–infant interactions. On her return to the USA, she received a position at Johns Hopkins University and sought to replicate her findings from the Uganda study in a Western society.

In her famous Baltimore study, Ainsworth followed 26 babies from birth to age 12 months. In her detailed observations of mother–infant dyads, she noticed how mother's sensitive, suitable response correlated with a more harmonious and sensitive relationship at age 8–12 months. Ainsworth also found that maternal responsiveness to the infant's crying during the first months of life is correlated with less crying in the months to come. This finding was met with skepticism, especially among learning theorists, who argued that attending to the baby's cry is likely to reinforce rather than stop the crying, and will not enhance preverbal, vocal, and gestural communication (Bretherton, 2003).

Ainsworth's Strange Situation Procedure

When the Baltimore study's babies reached the age of 12 months, Ainsworth developed a laboratory procedure to examine how they use their mothers as a secure base from which they can explore their environment (Ainsworth et al., 1978). This procedure was inspired by Harlow's study that illustrated how infant rhesus monkeys, when separated from their mothers and placed in a strange environment, were able to find comfort and explore their surroundings if their 'cloth mother' (a 'stepmother' made of wire covered with cloth) was available. But if the monkeys were in the presence of the 'wire mother' (a 'stepmother' made of steel wire that only fed the monkey), the infant monkeys showed elevated levels of fear and did not engage in exploration. Ainsworth's 20-min laboratory procedure became the well-known 'Strange Situation Procedure' (SSP), the gold standard for assessing infant attachment.

In the SSP, the 12–18 months infant and his or her caregiver are invited into a room equipped with toys that encourage play and exploration. During the session, the infant is separated from the caregiver and left in the room with a stranger, then reunited with the caregiver twice. Most of the infants stand near the door, some cry vigorously when the caregiver leaves the room. On her return, they approach her, seeking proximity and contact, without expressing negative behavior. When comforted by their caregiver, the infants resume exploration and play, hence the term *secure* (type B) attachment. Ainsworth found that secure attachment is associated with the attachment figures' sensitive responses throughout the first year of life. But not all infants display secure behavioral pattern. Some avoid the caregiver when she return, look away, or reject her bids for contact. These infants are referred to as having *insecure avoidant* (type A) attachment, masking negative affect and minimizing the importance of the caregiver as a source for comfort and security. Infants use this behavioral strategy in response to recurrent rejection by their caregiver, especially in times of need, which is a defensive strategy to avoid further rejection. A third group of infants, smallest in size, appears angry with the caregiver upon reunion, although they protest and show excessive distress when she leaves. The caregiver could not soothe the infant, who often resists when she tries to comfort him. These infants were named *insecure- resistant* or *insecure ambivalent* (type C). Insecure-ambivalent children exhibit proximity/contact maintenance with their caregivers mingled with excessive motor resistance to gain the inconsistently available caregiver's attention.

Ainsworth had a revolutionizing effect on how we understand infant–mother relationships and human relationships in general. Her insights fundamentally expanded attachment theory. She subjected Bowlby's theory to an empirical test by identifying patterns in mother–infant interaction that were implicated in differences in the quality of attachment relationships. She was first to note that parental sensitivity and responsiveness to the child's signals are key precursors of secure attachment. Indeed, both Bowlby and Ainsworth believed it was necessary to adapt scientific approaches, as they did, in order to validate the central concepts associated with attachment theory.

Other researchers and clinicians have taken these concepts further, proposing the *circle of security* model. According to Ainsworth and Bowlby, feelings of security equip the infant with a *secure base* from which he can depart for exploration and return to a *safe haven* when distressed and in need of emotional refueling. Jointly, secure base and safe haven create a *circle of security*. Social environments that do not provide a secure base or a safe haven generate a sense of *limited security* (Cooper et al., 2005). We suggest that *limited security* vis-à-vis insecure attachment may reflect more accurately the feelings and reality of some normative children who lack the full circle of security. In less favorable but not necessarily pathological environments, children who cannot fully rely on their caregivers' support and emotional availability, develop a sense of limited security.

Insecure attachment or *limited security* should be discussed in the context of what adaptation means. According to Hinde's (1982) position on conditional strategies, both mothers and babies are equipped to elicit not one set of interactions but a wide range of potential relationships compatible with specific environmental requirements. Main (1981) argued that both secure and insecure attachments are adaptive strategies to a given environmental condition, but insecure attachment has a higher adaptive cost for the infant and may be less functional in day-to-day life. Nevertheless, insecurity cannot be equated with psychopathology, and further research is needed to specify more concretely what such costs might be, namely the long-term implications for the well-being of the individual.

Mary Main and Disorganized Attachment

According to Main (1990), Ainsworth's student and collaborator, attachment classifications should be regarded as

behavioral strategies: the infant achieves the goal of maintaining proximity to the caregiver by planning his or her actions based on the caregivers' behaviors and responses. Despite the striking differences between secure and insecure babies, all experience consistent caregiving environments that enable them to develop an *organized attachment* strategy, adaptive to their environment and to the attachment figures' behaviors. But what happens when the attachment figure is also a source of fear, threat, or violence? Infants who are exposed to frightened/frightening parental behavior develop insecure attachment and may find it impossible to form an organized strategy toward their caregivers because they cannot depend on the caregiver's trust and security. These infants may withdraw and show insecure disorganized behaviors.

Main and Weston (1981) noticed that even in a normative sample 13% of infants could not be assigned to any of the three organized categories of attachment. In their parents' presence, unclassifiable infants showed 'contradiction in movement pattern' by expressing a range of disorganized, bizarre, stereotypical, unpredictable, and confused behaviors. Main and Hesse (1990) called it a vicious circle of 'fright without solution' that could lead to the collapse of organized attachment strategies. Disorganized attachment occurs more frequently with maltreated children. The effect of a disorganized attachment may go beyond infancy. Unlike insecure attachment, infant disorganized attachment was correlated with dissociative behaviors later in life, with difficulties in stress management (Van IJzendoorn et al., 1999), and with externalizing problems in childhood (Fearon and Belsky, 2011).

Although the SSP has yielded massive amounts of meaningful findings, its full-scale validity has been debated because of its reliance on laboratory settings alone, and for being restricted to the beginning of the second year of life, overlooking later developmental phases. Waters and Deane (1985) introduced a different method of assessing attachment security in infants and toddlers, known as the Attachment Q-Set (AQS). The AQS evaluates the child's behavior in his or her natural setting, by sorting a large number of cards that portray various behavioral characteristics of the child, with a focus on secure base behaviors. The sorting is compared with a prototypical profile of a secure child provided by experts, leading to a security score.

Assessing Attachment beyond Infancy

Following the development of secure or insecure behavioral patterns in infancy, children develop mental representations regarding their relationship with their caregivers, referred to as 'internal working models' (Bowlby, 1969). This change is facilitated by the development of new cognitive, linguistic, and social capacities, as attachment relationships move to what Main et al. (1985) referred to as 'the level of representations.' Bowlby (1982) termed this phase *goal-corrected partnership* (GCP). As children become increasingly able to express their feelings, thoughts, and motives, they realize that their parents may have goals and expectations different from their own. In such partnerships, both child and parent must consider the other's perspective and negotiate personal perspectives in order to gain a shared view of emotional and relationship issues. Individual differences in attachment security/insecurity determine the extent to which affective negotiations during conversations become congruent (Bowlby, 1973). The openness and autonomy that characterize child–parent conversations may vary in secure and insecure dyads (Bowlby, 1988): open communication enables the child to express a wide range of thoughts, feelings, and concerns, whereas non-open communication restricts his or her ability to express his or her needs and affects, excluding or over emphasizing meaningful emotional themes. Several methods focusing on verbal communication, parent–child dialogs or children's narratives, were developed to assess individual differences in attachment-based representations and dyadic negotiations (see Bretherton et al., 1990; Cassidy, 1988; Etzion-Carasso and Oppenheim, 2000; Gini et al., 2007; Oppenheim et al., 2007).

Parental State of Mind and Adult Attachment Interview

Main et al. (1985) hypothesized that adults' mental representations of their childhood attachment experiences crystallize into a relatively stable 'state of mind,' which may significantly affect the quality of their own child's attachment to them. The Adult Attachment Interview (AAI; George et al., 1984/1985/1996) was developed to capture such states. The AAI is a semi-structured interview in which the interviewee's childhood memories and current perceptions of these experiences are discussed. The interviewees describe attachment-related experiences from their childhood, including situations of emotional upset, illness, and separation from the parents. The AAI captures the speakers' current state of mind concerning their attachment representations stemming from childhood experiences with specified caring figures. Individuals may show a state of mind that is autonomous/free to explore (F), dismissing (Ds), or preoccupied/enmeshed (E). Individuals exhibiting errors in monitoring the discourse, when discussing traumatic or loss events, are rated as unresolved (U) with regard to a specific loss/trauma.

The AAI has been used extensively in studies of intergenerational transmission of attachment (Van IJzendoorn, 1995), demonstrating its potential strengths. Many questions remain open, including the extent to which the AAI coding system captures the underlying attachment-related representations for all life experiences and circumstances (see, for example, Koren-Karie et al. (2003) on the Absence of Attachment Representations (AAR) when experiencing catastrophic parental loss in childhood).

Antecedents of Attachment Security/Insecurity

Maternal Sensitivity

Ainsworth suggested that 'maternal sensitivity' shapes infant's secure attachment. Maternal sensitivity is the ability to read and interpret the baby's signals and to respond promptly and harmoniously. When such capacity is inadequate we may observe misinterpretations of the infant's behaviors resulting in disharmonious responses, conceived as maternal insensitivity.

Sensitive responses are likely to contribute to secure attachment. But not all studies yielded high correlations between attachment and maternal sensitivity (see *meta-analyses* by Goldsmith and Alansky, 1987; De Wolff and van IJzendoorn, 1997). Although maternal sensitivity contributes to secure attachment, it cannot be considered an exclusive factor, leaving a transmission gap, namely, unexplained variance in infant attachment security (Belsky, 2005).

Ainsworth focused on behavioral markers that underlie maternal sensitivity and explored it more broadly, at the level of the mother's state of mind and of her capacity to view the children's experiences from their point of view (Ainsworth et al., 1978): this is the capacity to consider the child's feelings, internal motives, and goals. Oppenheim and Koren-Karie (2009) referred to the mothers' insights regarding their children's internal experiences as 'maternal insightfulness.' They developed a new method for assessing insightfulness, and their recent research supports its discriminant and predictive validity. Mothers' capacity to consider the motives underlying their children's behaviors and emotional experiences in an insightful and open manner contributed significantly to the explained variance in attachment security above and beyond the mothers' interactive sensitivity. A more detailed discussion on the extensive research on sensitivity is beyond the scope of this article. For the latest findings on the subject see also the special issue of *Attachment and Human Development* (Grossmann et al., 2013) – 'Maternal Sensitivity: Observational Studies Honoring Mary Ainsworth's 100th Year.'

Continuity and Longitudinal Correlates: Attachment across the Life Span

As attachment theory became a central theoretical framework, longitudinal correlates of early relations began to occupy attachment research. But as Sagi-Schwartz and Aviezer (2005) noted, available longitudinal studies of attachment were inconsistent in their predictions from infancy to adulthood, concluding that children vary considerably in the degree to which attachment security in infancy remains consistent over time. Therefore, predicting later development based on early attachment experiences is a challenging and complex task that requires consideration of many issues pertinent to both longitudinal research and attachment theory.

An important issue that most longitudinal studies fail to address is the interface between coherent developmental change across time and susceptibility to environmental influences. Thompson (2008) suggested that both early experiences and contemporaneous events may influence developmental outcomes, and that the joint effect of the two may not be similar for different children. Furthermore, more stable living conditions would be more likely associated with continuity in attachment and its outcomes.

Another important issue, addressed by Sagi-Schwartz and Aviezer (2005), is whether early attachment should be conceived as a grand theory-based construct (Waters et al., 2000) predicting a broad spectrum of domains, or whether predictions should be restricted a narrower view, with a focus on attachment-based constructs (Grossmann and Grossmann, 1990). Longitudinal studies have applied both broad and narrow constructs (Goldberg et al., 1999), which may account for the great variability in research findings (Thompson, 2008).

Sagi-Schwartz and Aviezer (2005) also noted the need for a closer study of networks of attachment relations. They propose to explore all of the child's relationships and test whether the cumulative effect of the attachment network is a more powerful predictor of future development than each separate attachment relationship by itself. Specifically, is there a dominant attachment figure within a hierarchy of relationships that has a more pronounced effect on future personality development than do other attachment figures? It is not clear yet whether such influences are organized into a generalized personality construct (and if so, how) or into relationship-specific attachment representations (see more on this issue: Furman and Simon, 2004).

More work is necessary to determine whether and how experiences with different attachment figures exert differential/specialized effects on children, contributing unique domain-specific components to personality development (Grossmann et al., 2005; Oppenheim et al., 1988; Sagi-Schwartz and Aviezer, 2005). In all, existing research suggests that the developmental trajectories from infancy to adulthood are multidetermined and multifaceted. Various conceptual formulations, some contradicting each other, compete for settling the issues of continuity/discontinuity and stability/instability. Sagi-Schwartz and Aviezer (2005) noted that when pioneers in the field began their studies in the early 1970s, they were concerned mainly with the procedure for assessing infant attachment. Longitudinal research evolved as a by-product of these exciting developments and was not based on a priori conceptual or methodological planning. Much of this research was based on hypothesis-generating rather than hypothesis-testing models, and therefore many of the issues mentioned above remain to be addressed. Finally, the recently proposed concept of 'differential susceptibility' (see below) may be used also as an explanatory mechanism for inconsistencies in longitudinal research that often neglect to consider the genetic makeup of both parents and children.

Attachment and Genetics

Two lines of research on the interaction between attachment and genetics are noted. The first follows behavioral genetic models. In one such study, Bokhorst et al. (2003) found that 52% of the variance in attachment security was accounted by environmental factors and 48% by unique environmental factors/measurement errors, leaving no room for genetic effects. But genetic factors played a significant role in explaining 77% in temperamental reactivity, and differences in temperamental reactivity did not correlate with attachment concordance.

The second line of research follows molecular genetics and the study of gene–environment interaction. It examines how similar environments may have differential effects on children because of the children's genetic makeup. The idea of differential susceptibility (Belsky, 2005) which is gaining momentum in current research, suggests that because of

genetic markers some children are more or less susceptible to both positive and negative effects of similar caregiving practices. Bakermans-Kranenburg and van IJzendoorn (2007) found that interactions between specific susceptibility markers of the DRD4 gene and unfavorable environmental factors explain individual differences in negative outcomes, such as risk for disorganized attachment. They also present evidence of more positive outcomes when susceptible children are exposed to favorable environments. How does this relate to Bowlby's work? Bowlby did not use the contemporary notation of genetic X environment interaction. He did pay attention, however, to the possible influences of genetic factors on human development: *Psychoanalysts like the nurseryman should study intensively, rigorously, and at first hand, the nature of the organism, the properties of the soil and the interaction of the two* (Bowlby, 1940: p. 23).

Attachment-Based Interventions

Attachment theory has also inspired the clinical arena and the field of intervention, and various attachment-based interventions became available. For example, Video-Feedback to Promote Positive Parenting and Sensitive Discipline (VIPP-SD), (Juffer et al., 2008; http://www.marinusvanijzendoorn.com/video-feedback-intervention-vipp); Attachment and Biobehavioral Catch-up (ABC) (Dozier et al., 2005) targets parental behaviors among high-risk and foster parents (http://abcintervention.com/); Minding the Baby (MTB) (Sadler et al., 2013), an interdisciplinary, intensive home-visiting program that focuses on first-time, young, at-risk mothers and their families (http://mtb.yale.edu/index.aspx); and Circle of Security (Cooper et al., 2005), a group psychoeducational interventions seeking to alter attachment interaction in high-risk caregiving dyads (http://circleofsecurity.net). Each of these attachment-based interventions has a different focus and requires further research support. In their *meta-analysis*, Bakermans-Kranenburg et al. (2003) showed that short-term interventions with a behavioral focus were more effective than long-term intervention, suggesting that 'less is more.' Finally, interventions that succeeded in improving parental sensitivity were more effective in enhancing attachment security.

Summary

Bowlby proposed his attachment theory based on observations of the difficulties experienced by children exposed to adverse environments, mainly neglect, abandonment, and institutionalization. In the last decades, however, attachment theory has evolved in various directions, including both normative and at-risk children and settings. Today attachment theory reaches into such areas as representations, mentalization, caregiving, marital relationships and divorce, child care, foster care and adoption, religious orientation, intervention, and recently even political psychology (Sagi-Schwartz, 2012). These are extensively reviewed in two editions of the *Handbook of Attachment* (Cassidy and Shaver, 1999/2008). The *Journal of Attachment and Human Development*, under the editorial leadership of Howard Steele and Jude Cassidy, is another important platform for discussing attachment-related issues.

In closing, we wish to call attention to one direction that represents Bowlby and Ainsworth's integrated perspective of attachment theory and research over the past decades. It relates to children at profound risk in their environment. Recently an international group of researchers produced a 'Consensus Statement on Group Care for Children and Adolescents' also endorsed as a policy statement of the American Orthopsychiatric Association. Accordingly, *every child has a basic right and need to grow up in a safe home with a stable continuous relationship with at least one adult who is a trusted, committed parent figure. Group settings should not be used as living arrangements, because of their inherently detrimental effects on the healthy development of children, regardless of age* (Dozier et al., 2014).

Integration and Multiculturalism: Focus on Western Europe

Tariq Modood, University of Bristol, Bristol, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Examining the concept of social integration, I challenge the view that multiculturalism emphasizes difference at the expense of commonality, separatism rather than mixing, group rather than national identities, relativism rather than a defense of democratic values. I argue that multiculturalism is a mode of integration, which can be contrasted with other modes such as assimilation, individualist-integration, and cosmopolitanism, and like the others it is based on the core democratic values of liberty, equality, and fraternity/unity. While multiculturalism involves a respect for minority identities, this is not at the expense of national identities, as long as the latter are remade to include minority as well as majority identities. The discussion relies mainly on examples from Western Europe.

There is much confusion about what multiculturalism is. This situation is partly because 'multiculturalism' is too often defined by its critics, whose sole purpose is to create a straw man to knock down. But it is also because both its critics and some of its defenders falsely oppose multiculturalism with integration; and the confusion also partly stems from the fact that there is more than one form of multiculturalism and they relate to integration in different ways. I will clarify the key terms of assimilation, integration, cosmopolitanism, and multiculturalism. My argument is that discourses of integration and multiculturalism are exercises in conceptualizing post-immigration difference or identities and as such operate at three distinct levels: as an (implicit) sociology; as a political response; and as a vision of what is the whole in which difference is to be integrated.

Integration

The need for integration arises when an established society is faced by some people who are perceived and treated unfavorably from standard members (and typically who also perceive themselves as 'different' though not necessarily in a negative way). This may relate to different areas or sectors of society and policy, such as employment, education, housing, and so on. Someone is integrated into the labor market, for example, when she or he is able to enjoy equality of opportunity in accessing jobs and careers, including accessing the education and training necessary to compete for such jobs. Additionally, integration would require that the labor market not be segmented into different parts with radically different monetary rewards and working conditions for those with broadly similar qualifications and experience. The labor market is particularly relevant, where the segmentation is not, formally or informally, based on criteria such as race, ethnicity, religion, and so on; namely the categories of 'difference'. Avoidance of segmentation of this sort can be more generally applied to other sectors such as education and housing. A core idea of integration is equality of opportunity in an unsegmented society where no channeling into or away from a sector of society takes place based on criteria such as race and ethnicity. Integration has a number of components based on opportunities to participate that are context specific and need to be secured by law and policy initiatives. However, integration also has a subjective and symbolic dimension. This dimension will have some context-specific features, but also has a more general or macro character. It includes how the rest of the country perceives a minority and how members of a minority perceive their relationship to society as a whole. Sectoral integration, however, is not full integration without some degree of subjective identification with the society or country as a whole. This requires a feeling of belonging, and the acceptance by the majority that the minority is a full member of society. This is what the Commission on Multi-Ethnic Britain called 'a sense of belonging' (CMEB, 2000: Introduction).

An individual may choose to integrate or not, and may be given opportunities to participate or not. My interest here is not on individual choices and opportunities themselves but rather the level of groups or society as a whole. A sense of belonging is dependent on how others perceive and treat you, not just as an individual but also as a member of a racial group or ethno-religious community. Each policy area (e.g., whether it is issues of qualification levels or residential segregation) will have its own imperatives and difficulties. (Different groups may integrate to different degrees across sectors. For example, Jews in Britain are highly integrated in relation to employment but are the most segregated religious minority (Peach, 2007).) There is, however, also a general understanding that we have, as members of society, about what our society is and what it is to be a member – a macro-symbolic conception of society and of integration. Such general conceptions inform popular understanding as well as political ideas and the general terms of policy paradigms. Hence, it has been said by a Commission on these topics in Quebec, "the symbolic framework of integration (identity, religion, perception of the Other, collective memory, and so on) is no less important than its functional or material framework" (Bouchard and Taylor, 2008). Indeed, the sense of 'crisis' about multiculturalism and integration is operating at this macro-symbolic level. This is evident when one considers how few in any country are the policies that could be said to be about integration or how small the funds involved compared to the headline importance that the issues regularly achieve. In thinking about policy paradigms of a general ethos or

orientation at a national level it is therefore important to engage at this macro-symbolic level.

I consider this larger, macro-symbolic sense of integration and implied policy paradigms in terms of four modes of integration (summarized in **Table 1**), namely, assimilation, individualist-integration, and two versions of multiculturalism, one of which I will call cosmopolitanism. (The concern here is not primarily in relation to socioeconomic integration, for which see Loury et al. (2005) and Heath and Cheung (2007).) Each offers their own distinctive take on freedom, equality, and civic unity (what might be called 'fraternity' or solidarity), the core values of European democracy. (In doing so I follow Charles Taylor's treatment of the concept of secularism (Taylor, 2009), though without claiming that he would use it as I do in relation to integration.) Different interpretations and prioritizations of these concepts suggest embryonic paradigms. The issue or 'problem' these paradigms are addressing is post-immigration 'difference' (Modood, 2007). 'Difference' primarily refers to how people are identified: how they identify themselves (e.g., as 'white', 'black', 'Chinese', 'Muslim,' etc.), how they identify others, and how they are identified by others.

These identities fall (not necessarily unambiguously or discretely) within the fields of 'race', ethnicity, religion, culture, and nationality as various forms of difference. The problem, then, is how to integrate difference, by which I mean the process whereby difference ceases to be problematic. It is commonly said that we must distinguish between multiculturalism as social description and multiculturalism as political understanding of those social facts (e.g., Malik, 2010). Interestingly, the same could be, but is rarely said about class/Class, nation/Nation, or gender/Gender too are cases which could be distinguished in terms of social description, on the one hand, and as political understanding of those facts on the other hand. Yet, this is rarely done and the distinction is specially applied to multiculturalism. The distinction, however, is of limited value because social description and sociological concepts are not normally politically neutral. The concepts I analyze below, then, are normative and policy oriented but they presuppose an understanding of what the social phenomenon is that demands a political response. The problem, then, is how to integrate difference or to put it another way, the processes whereby difference ceases to be problematic. I shall consider four modes of integration (summarized in **Table 1**).

Modes of Integration

Assimilation, or one-way integration, is where the processes affecting change and the relationship between social groups are largely one way with the result being one where the newcomers do little to disturb the society they are settling in and become as much like their new compatriots as possible. (When the US sociologists use the term 'assimilation', they usually mean what is meant by integration in the UK, as in the 'segmented assimilation' proposed by Portes and Zhou (1993).) By erasing difference it is may be thought that the occasions for discrimination and conflict are not allowed to take root. While 'assimilation' as a term has been dropped in favor of 'integration', even today, some European politicians use the term 'integration' they consciously or not are referring to what I have defined as assimilation (Fekete, 2008). The use of these terms

Table 1 Four modes of integration[a]

	Assimilation	*Individualist-Integration*	*Cosmopolitanism*	*Multiculturalism*
Objects of policy	Individuals and groups marked by 'difference'.	Individuals marked by 'difference', especially their treatment by discriminatory practices of state and civil society.	Individuals marked by 'difference', especially their treatment by discriminatory practices of state and civil society, and societal ideas, especially of 'us' and 'them'.	Individuals and groups marked by 'difference', especially their treatment by discriminatory practices of state and civil society, and societal ideas, especially of 'us' and 'them'.
Liberty	Minorities must be encouraged to conform to the dominant cultural pattern.	Minorities are free to assimilate or cultivate their identities in private but are discouraged from thinking of themselves as minority, but rather as individuals.	Neither minority nor majority individuals should think of themselves as belonging to a single identity but be free to mix and match.	Members of minorities should be free to assimilate, to mix and match or to cultivate group membership in proportions of their own choice.
Equality	Presence of difference provokes discrimination and so is to be avoided.	Discriminatory treatment must be actively eliminated so everyone is treated as an individual and not on the basis of difference.	Antidiscrimination must be accompanied by the dethroning of the dominant culture.	In addition to antidiscrimination the public sphere must accommodate the presence of new group identities and norms.
Fraternity	A strong, homogeneous national identity.	Absence of discrimination and nurturing of individual autonomy within a national/European, liberal democratic citizenship.	People should be free to unite across communal and national boundaries and should think of themselves as global citizens.	Citizenship and national identity must be remade to include group identities that are important to minorities as well as majorities; the relationship between groups should be dialogical rather than one of domination or uniformity.

[a]In all cases it is assumed that a backdrop of liberal democratic rights and values are operative to a large degree and what is highlighted here is in addition or in interaction with them.

in public discourse must not be taken therefore at their face value but critically inspected.

In the three nonassimilative modes of integration, processes of social interaction are seen as two way, where members of the majority community as well as immigrants and ethnic minorities are required to participate; so the latter cannot alone be blamed for failing to, or not trying to, integrate. The established society is the site of institutions – including employers, civil society and the state – in which integration has to take place, and accordingly they must take the lead. The new (prospective) citizens' rights and opportunities must be made effective through antidiscrimination laws and policies. We need, however, to distinguish between *individualist-integration* and *multiculturalism*. Individualist-integration sees the need for institutional adjustments in relation to migrants or minorities but sees these as only individual claimants and bearers of rights as equal citizens (Barry, 2001). Minority communities may exist as private associations but are not recognized or supported in the public sphere.

Multiculturalism is where processes of integration are two way and as involving groups as well as individuals. Moreover, the processes may work differently for different groups (CMEB, 2000; Parekh, 2000; Modood, 2007). In this understanding, each minority group is distinctive, and thus integration cannot consist of applying a single template to them (hence the 'multi' in 'multiculturalism'). The 'culturalism' – by no means a happy term either in relation to 'culture' or 'ism' – refers to that the groups in question are likely not just to be marked by newness or phenotype or socioeconomic location but by certain forms of group identities. The groups are not merely 'newcomers' or 'black' or 'inner-city dwellers' but have a sense of subjective identification, a sense of 'we'. The integration of groups is in addition to, not as an alternative to, the integration of individuals, antidiscrimination measures, and a robust framework of individual rights.

Multiculturalism, like most concepts, takes different form in different contexts and at different times. For example, it has been differently understood in the Netherlands than in Britain (Joppke, 2004; Koopmans et al., 2005) and in Quebec compared to in Anglophone Canada (Bouchard and Taylor, 2008: chapter 6). The meaning of any mode of integration is subject to debate and contestation and its policy originators may start with one meaning, as Roy Jenkins did in relation to race and culture, and others may push it or extend it in other directions by, say, making religion central, as Muslims in Britain have done (Modood, 2005).

Among what is central to multiculturalism is the concept of equality, as indeed it is to other conceptions of integration. The key difference between individualist-integration and multiculturalism is that the concepts of group and of 'multi' are essential to the latter. Postimmigration minorities are groups differentiated from the majority society or the norm in society by two kinds of processes. On the one hand, by negative 'difference' with alienness, inferiorization, stigmatization, stereotyping, exclusion, discrimination, racism, and so on. On the other hand, by the senses of identity that groups so perceived have of themselves. The two together are the key data for multiculturalism. The differences at issue are those perceived both by outsiders or group members – from the outside in and from the inside out – and constitute not just some form of distinctness, but a form of alienness or inferiority that diminishes or makes difficult equal membership in the wider society or polity.

Multiculturalism has recently been defined as "where ethnocultural-religious minorities are, or are thought of, as rather distinct communities, and where public policy encourages this distinctiveness" (Emmerson, 2011). This, however, is only a third of it. Multiculturalism allows those who wish to encourage such distinctiveness to do so; but it also seeks forms of social unity that are compatible with this, what Hartmann and Gerteis (2005) call 'new conceptions of solidarity', grounded in a concept of equality (Bouchard and Taylor, 2008). Each mode of integration must be understood in terms of its interpretation of free choice, equality, and fraternity. Characterizations of multiculturalism that subtract its emphasis on unity are extremely common but incomplete.

Further Unpacking Integration and Multiculturalism

Multicultural accommodation of minorities, then, is different from individualist-integration because they explicitly recognize the social reality of groups, not just of individuals and organizations. There may, however, be considerable complexity about what is meant by social reality of groups or 'groupness' here. Ideas of groups as discrete, homogeneous, unchanging, bounded populations are not realistic when we are thinking of multicultural recognition (Modood, 2007: pp. 93–97). This discussion leads us to cosmopolitanism.

Cosmopolitanism emerges by accepting the concept of difference while critiquing or dissolving the concept of groups (Waldron, 1991). (Here I do not mean the ethical view that one should be a citizen of the world, rather I am characterizing a mode of integration within a country that emphasizes a mixing of people from all over the world as in the expression 'London is a cosmopolitan city'. British sociologists sometimes use the term 'multiculture' but this clearly has not carried over into public discourse. It has been suggested to me that the term 'interculturalism' best fits here but the place where it is most used in relation to national politics, Quebec, it is closer to what here I call 'individualist-integration'. More generally, it is not clear that 'interculturalism' includes anything that is not or cannot be included in multiculturalism (see Meer and Modood, 2012). I did also consider the term 'diversity' but it is either too descriptive and generic and does not pick out a mode of integration, or has been appropriated as 'diversity management' by human resource professionals.) Disagreement about the extent to which postimmigration groups exist and/or ought to exist and be given political status means that there are two kinds of multiculturalism (Modood, 1998; Meer and Modood, 2009). While in public discourse, as well as in academia, one or both are referred to as multiculturalism, I will reserve the term 'multiculturalism' for the sociological and political position in which groups are a critical feature. (This is how the term has been used by the leading political theorists such as Taylor (1994), Kymlicka (1995), and Parekh (2000) and, by the Canadian government; it is also consistent with CMEB (2000) and other exponents of multiculturalism – see Modood (2007: pp. 14–20) for details.)

Cosmopolitanism positively valorizes 'difference' (or pragmatically accepts it) but denies that groups exist or, alternatively, exist but should not be politically recognized. The contention is that in the early stages of migration and settlement, especially in the context of a legacy of racism, colonialism, and European supremacism, forms of social exclusion created or reinforced certain forms of groupness such as white and black. However, as a result of social mixing, cultural sharing, and globalization in which dominant identities of modernity (such as of race and nation) are dissolving, people have much more fluid and multiple identities, combine them in individual ways and use them in context-sensitive ways (Hall, 1992a). For example, the ways that Caribbean-origin Britons have socially blended into a 'multiculture' and have sought conviviality and sociability rather than separate communities may perhaps not be fully captured as a form of individualistic integration (Gilroy, 2000). While remaining economically marginal and overrepresented in relation to the social problems associated with deprived inner city areas, they have become a feature of popular culture in terms of music, dance, youth styles, and sport (Hall, 1998). To the extent that football teams, Olympiads, and television programmes such as *The X Factor* are central to popular and national identities, Caribbean-origin people are placed at the center of British national imaginaries.

Moreover, Britain and most other countries in Western Europe have recently experienced and are experiencing a new wave of immigration and will continue to do so, including from within the European Union. Given the diversity of the locations from where migrants are coming, the result, it is argued, is not communities, but a churning mass of languages, ethnicities, and religions, all cutting across each other and creating a 'super diversity' (Vertovec, 2007). This may be setting a pattern for the future, and it may be allied to a further argument that globalization, migration, and telecommunications have created populations dispersed across countries that interact more with each other, and have a greater sense of loyalty to each other, than they might to their fellow citizens.

In what ways does cosmopolitanism go beyond individualist-integration? Its distinctive ethos is that we should value diversity and create the conditions in which it is individually chosen. We should oppose all forms of imposition of group identities on individuals and therefore the ideas, images, and prejudices by which individuals are inferiorized or portrayed as threatening and so excluded from full membership of society, and we should not require assimilation or conformity to dominant group norms. Yet, a requirement of communal membership can also be oppressive of individuals and their life chances (Appiah, 1994). Inherited or ascribed identities that slot people into pigeonholes not of their choosing should be refused. These ascribed identities not only reduce the options of the kind of person one can be but divide society up into antagonistic groups. (British exponents of this view tend, however, to put some communal identities in a normative, privileged position. This particularly applies to political blackness and to some extent to noncultural and nonreligious political identities generally (Modood, 1994).) Cosmopolitanism, then, is a conception of multiculturalism as maximum freedom, for minority as well as majority individuals, to mix with, borrow, and learn from all (whether they are of one group or another) so individual identities are personal amalgams of bits from various groups and heritages, and there is no one dominant social identity to which all must conform. The result will be a society composed of a blend of cultures, a 'multiculture'.

While this is an attractive image of contemporary society and blends easily with the ideas of liberal democracy, it has only a partial fit with London today, let alone many parts of Britain and continental Europe. In some towns and cities, such as in northern England, there is not a diversity of ethnic groups but often just two (e.g., Asian Muslims and whites) and minority individuals do not float across identities, mixing, and matching, but have a strong attachment to a one or few identities. For example, most British Muslims seem to think of themselves in terms of 'Muslim' and/or 'British' (usually both) (Travis, 2002). The fact of super diversity is emerging alongside rather than displacing the fact of settled, especially postcolonial, communities, who have a particular historical relationship with Britain, and the political significance of such communities. Similarly, there are other communities in other European countries with their own historical significance such as Maghrebians (migrants from the northern countries of Africa) in France and the Turks in Germany. Moreover, some groups continue to be much larger than others, and stand out as groups – in their own eyes and those of others. Muslims, for example, seem to be in this category across much of Western Europe regardless of the degree of conviviality or super diversity that might be present.

That is not to say that such minority identities are exclusive. Successive surveys have shown that most Muslims in Britain strongly identify with being Muslim but the majority also identify as British. Indeed, they are more likely to identify with 'British' and say they have trust in key British institutions than non-Muslims. Several researchers (Heath and Roberts, 2008; Gallup, 2009) found the same in Germany, albeit less so in France though Pew (2006) found much higher levels of national identification in France than other western European countries.

Postimmigration hyphenated identities, such as British-Indian, have become as commonplace in Britain as they have been in the United States for decades. Similarly, diasporic links as described above certainly exist, and are likely to increase, but the net result is not an inevitable erosion of national citizenship – British African-Caribbeans and South Asians have families in their countries of origin and in the US and Canada, but there is little evidence that most branches of those families do not feel British, American, or Canadian (e.g., Modood, 2007; Bloemraad, 2006). Indeed, studies show that the more multiculturalist countries achieve higher levels of national identification among migrants and the second generation (Esses et al., 2006; Wright and Blooemrad, 2012).

An important point of difference, then, between the concepts of individualist-integration and multiculturalism proper is that for the latter, the postimmigration minorities are not of one kind but are a 'multi'. For example, some people will identify with a color identity like 'black' but there will be others for whom national origin identities (like 'Turkish'), or a regional heritage (like 'Berber'), or a religious identity (like 'Sikh') may be much more meaningful, expressing forms of community and ethnic pride and struggling for recognition and

inclusion. And of course these minority identities will interact with wider, societal identities – 'woman', 'working class', 'Londoner', 'British' – in differing ways, expressing the different experiences, locations, and aspirations of different groups. So, both the alternative models of multiculturalism as cosmopolitanism and what may be called ethno-religious communitarianism have some grounding and meet the political aspirations of some minority groups. Neither works as a comprehensive sociological or political model and they should be viewed as complementary (Modood, 1998; CMEB, 2000; Modood and Dobbernack, 2011). Moreover, while recognition of ethnic or religious groups may have a legal dimension, for the most part, it will be at the level of civic consultations, political participation, institutional policies (e.g., schools and hospitals), discursive representations, especially in relation to the changing discourses of societal unity or national identity, and their remaking.

Regardless of the extent to which recognition of minority identities in this way is formal or informal, led by the state or the semiautonomous institutions of civil society, it does not challenge, let alone displace, individual rights and the shared dimensions of citizenship. There may however be genuine concern that some groups at a particular time and in some areas are becoming too inward looking. Where the concern is primarily about a lack of positive mixing and interaction between groups at a local level, community cohesion measures – for example, a Christian school offering places to non-Christians or twinning with a non-Christian school – may be an appropriate response (Cantle, 2001). Where the concern is about self-conceptions and discourses more generally, the issue will be about the national or societal identity. While such inwardness has never been part of any theory or policy of multiculturalism, it is clear that it is a fundamental anxiety of the critics of multiculturalism, many of whom go as far as defining multiculturalism in terms of separatism. (A review of the American social science literature found that "[t]he most common conception of multiculturalism in both scholarly circles and popular discourse is a negative one, having to do with what multiculturalism is not or what it stands in opposition to. Multiculturalism, in this usage, represents heterogeneity as opposed to homogeneity, diversity as a counterpoint to unity" (Hartmann and Gerteis, 2005: pp. 219). They found that if they looked at exponents, as opposed to critics, of multiculturalism, such simplistic dichotomies were unsustainable and they concluded: "multiculturalism is best understood as a critical-theoretical project, an exercise in cultivating new conceptions of solidarity in the context of dealing with the realities of pervasive and increasing diversity in contemporary societies" (pp. 221–222).) It is therefore important to emphasize that accommodation of ethno-religious communities is a mode of integration, and that it, no less than hostility to minorities or other modes of integration, should be examined as a possible contributory cause of exclusion and integration (Banting and Kymlicka, 2008).

Multiculturalism Is Not Dead

This unpacking of what I mean by 'multiculturalism' is also helpful in understanding those who say that multiculturalism has failed (Weldon, 1989; see Presseurop (2010) for Angela Merkel's speech on the failure of *multikulti*) or that multiculturalism is dead (Cameron, 2011). They may mean to endorse assimilation, individualistic integration, or cosmopolitanism. At the same time they are acknowledging and possibly reinforcing the sociological reality of group difference because their lament is that some groups (especially Muslims) are clearly visible as distinct groups when they should not be; they attribute this fact to a separatist tendency in the groups, encouraged by allegedly multiculturalist policies. The accusatory discourse that 'some groups are not integrating' may actually be reinforcing group identities and therefore contributing to the social conditions that gives multiculturalism a sociological pertinence. Moreover, it is not just at the level of sociology that antimulticulturalists may find themselves using multiculturalist ideas; even while deploying an antimulticulturalist discourse politicians may enact multiculturalist policies. Politicians may, for example, continue with group consultations, representation, and accommodation. The latter have actually increased. The British government has found it necessary to increase the scale and level of consultations with Muslims in Britain since 9/11, and, dissatisfied with existing organizations, has sought to increase the number of organized interlocutors and the channels of communication. Avowedly antimulticulturalist countries and governments have worked to increase corporatism in practice, for example with Nicholas Sarkozy's creation of the Conseil Francais du Culte Musulman in 2003 to represent all Muslims to the French government in matters of worship and ritual. Similarly, Islamkonferenz was established in Germany in 2005 as an exploratory body, but has an extensive political agenda. These bodies are partly top-down efforts to control Muslims or to channel them into certain formations and away from others. Nevertheless, such institutional processes cannot be understood within the conceptual framework of assimilation, individualist-integration, or cosmopolitanism. These top-down bodies are normatively less than the best of multiculturalism but they clearly are deploying a multiculturalist mode of integration and their presence offers the possibility of movement toward a more egalitarian multiculturalism.

The analytical framework offered helps us also to understand those who say they welcome diversity but seem to be in agreement with critics of political multiculturalism. Critics point to the public assertion of strong group identities to achieve certain policies and/or to demand differential treatment. Some respond to this criticism by noting that multiculturalism is working in their neighborhoods. Such proponents say that neighborhoods are multiethnic and people do not just live peaceably side by side, but mix freely and value mixing. Yet such views do not imply support for strong group identities and related policies; on the contrary, their success may be seen to be dependent on the absence of the latter. (Hence the irony that antimulticulturalists like President Sarkozy are trying to create corporate representations for Muslims in France; while prodiversity authors call for the cessation of government meetings with Muslim community leaders (Sen, 2006; Malik, 2011).) Hence, while this is a reasonable response in its own terms it does not counter the above criticism of multiculturalism and in fact may share it. It is the group-based

multiculturalism that has become unpopular and is what critics have in mind so that criticism is left standing. The weakness of the rebuttal though is obscured by the fact that advocates of neighborhood 'multiculturalism' are in practice referring to what I call 'cosmopolitanism'. Another way of putting this is to say that cosmopolitans may be as critical of an ethno-religious communitarianism as antimulticulturalists.

Can integration of all postimmigration formations, however, be achieved without group-based multiculturalism (Modood, 1998, 2007)? Moreover, a group-based multiculturalism, where group membership is voluntary, may be part of the future in an unintended way as it is highly compatible with the Prime Minister Cameron's vision of a 'Big Society' in which civil society associations based on locality and faith, including interfaith groups, take over some responsibilities currently undertaken by state agencies. A flagship policy of the Big Society agenda is the state funding to create new community-based nonstate schools called 'free schools'. Over a quarter of these are led by religious groups; those that started in September 2011 included two Jewish, a Hindu, and a Sikh school (Vasagar, 2012). Of the 102 schools approved for funding in July 2012, three were Jewish, one was Hindu, four were Sikh, and four were Muslim (BHA, 2012). It is difficult to see how the new Big Society is a break with what is rejected as 'state multiculturalism' (Cameron, 2011). The same trend is found in France, where three Muslim schools have joined the many thousands (mainly Catholic) of state-supported religious schools (Akan, 2009: pp. 246–247), and in Germany, where there are no state funded religious schools but where Islam is increasingly incorporated in instruction (The Local, 2011; see also DIK, 2009).

The analysis offered here of related macro-symbolic ideas and policy paradigms, each of which consists of a model of society and normative political ideas, includes a sense of unity or fraternity. Modes of integration are not just about sociology or politics but include ideas, however inchoate, of ourselves as a social unity (as displayed at the bottom of **Table 1**). For assimilationists, this consists of a strong, homogeneous national identity. Individualist-integration emphasizes the liberal and democratic character of the national polity. Cosmopolitanism is uneasy with the national, an identity that demands allegiance from all citizens, while creating boundaries between ourselves and the rest of the world. With multiculturalism comes a positive vision of the whole remade so as to include the previously excluded or marginalized on the basis of equality and sense of belonging. It is at this level that we may fully speak of multicultural integration or multicultural citizenship (Taylor, 1994; Parekh, 2000; Modood, 2007). This third level of multiculturalism, incorporating the sociological fact of diversity, groupness, and exclusion, but going beyond individual rights and political accommodation, is perhaps the level that has been least emphasized. Or at least that is how it seems to many whose understanding of multiculturalism, sometimes polemical but sometimes sincere, is that multiculturalism is about encouraging minority difference without a counterbalancing emphasis on cross-cutting commonalities and a vision of a greater good. This has led many commentators and politicians to talk of multiculturalism as divisive and productive of segregation.

Theorists of multiculturalism (Taylor, 1994; Parekh, 2000), related policy documents (CMEB, 2000), and national enactments (citation), are universally regarded as pioneers and exemplars of state multiculturalism and all appealed to and built on an idea of national citizenship. From a multiculturalist point of view, though not from that of its critics, the recent emphasis on cohesion and citizenship, what has been called 'the civic turn' (Mouritsen, 2008), is a necessary rebalancing of the political multiculturalism of the 1990s. This form of multiculturalism largely took the form of accommodation of groups while being ambivalent about national identity (Meer and Modood, 2009). (In the 1990s cosmopolitanism and multiculturalism in Britain began to be linked to a national identity and its modernization, to, for example, 'Cool Britannia' and 'rebranding Britain' (Leonard, 1997) but others welcomed globalization as an era of the 'postnational' (Hall, 1992b; Soysal, 1994).) This does not invalidate the analysis that integration without institutional accommodation is unlikely to be successful. Indeed, for multiculturalists, a renewed national identity has to be distinctly plural and hospitable to the minority identities. It involves 'rethinking the national story' with the minorities as important characters; not obscuring difference but weaving it into a common identity that all can see themselves in and giving all a sense of belonging to each other (CMEB, 2000: pp. 54–56; Modood, 2007: pp. 145–154).

Conclusion

It may be the case that all the attempted models of integration, especially national models, are in crisis. Certainly many perceive each as having failed and none have brought about equality of opportunity measured in terms of socioeconomic indicators, nor full acceptance of minorities as full cocitizens and conationals. We can, however, have a better sense of what the issues are and so what needs to be done if, firstly, we recognize that discourses of integration and multiculturalism are exercises in conceptualizing postimmigration difference and as such operate at three distinct levels: as an (implicit) sociology, as a political response, and as a vision of what is the whole in which difference is to be integrated. Depending upon the sociology in question, certain political responses are possible or not, or, more reasonable or less. The sociological and political assumptions are thus mutually dependent.

Secondly, I have offered a framework in which four distinct political responses (assimilation, individualist-integration, cosmopolitanism, and multiculturalism) can be understood in terms of liberty, equality, and fraternity/unity, thereby bringing out what is of merit in each mode as well as the ways in which it is deficient (summarized in **Table 1**). They illuminate each other and each successive position attempts to include what is thought to be missing from the predecessor. Each position can in principle be attractive from different perspectives: some ethnic minorities may wish to assimilate, some to have the equal rights of integrated citizens, some to maintain the cultural differences of their group identities, and some to be free to choose

cosmopolitan mixed identities suiting the roles they take on in a more diverse society. Equally, host communities may look on different groups of migrants in all these different ways. Assimilation may be more appropriate in terms of national language acquisition before naturalization; individualist-integration may provide the model for nondiscrimination in the labor market; yet multiculturalism may be the basis for supplementing electoral representation (where minorities are underrepresented) and in creating new attitudes of inclusivity and in rethinking national identities. Each approach has a particular conception of equal citizenship but the value of each can only be realized if it is not imposed but is the preferred choice of minority individuals and groups, who, of course, being a 'multi', are bound to choose differently. Thus no singular model is likely to be suitable for all groups. To have a reasonable chance of integrating the maximum number of members of minorities, none of these political responses should be dismissed. Communitarian multiculturalism, then, has to be understood in terms of meeting the liberty, equality, and unity requirements that the other modes of integration fall short on. Yet, perhaps the ultimate meaning of multiculturalism, lets call it, multicultural citizenship, is not as one mode of integration but as the perspective that allows all four modes of integration their due.

Ethno-religious communitarianism may currently be viewed as undesirable by European publics and policymakers but given how central Muslims have become to the prospects of integration on a number of fronts, it is unlikely that integration can be achieved without some element of this approach (Levey and Modood, 2009; Triandafyllidou et al., 2012). Perceptions of Muslims as groups, by themselves and by non-Muslim majorities, are hardening. So the key question is whether they are to be stigmatized as outsiders or recognized as integral to the polity.

Finally, we must not overlook the third analytical level, which in many ways is not primarily about minorities but about the majority. The enlargement, hyphenation, and internal pluralizing of national identities is essential to an integration in which all citizens have not just rights but a sense of belonging to the whole as well as to their own 'little platoon' (Burke, 1982: p. 135). ("To be attached to the subdivision, to love the *little platoon* we belong to in … we proceed toward a love to our country, and to mankind" (Burke, 1982: p. 135).)

Abstract

Social integration refers, in the first instance, to the extent and intensity of the interlinkages among the constituent parts of a social unit. This definition applies to all types of social units – a small group like a family; a gang or an Internet newsgroup; an organization like a firm, an administration or a nongovernmental humanitarian organization; a community like a neighborhood, a local church community, a local business community, or a local ethnic community; or a society like a local society, a national society, a supranational society, for example, European society or even world society.

Social integration refers, in the first instance, to the extent and intensity of the interlinkages among the constituent parts of a social unit. This definition applies to all types of social units – a small group like a family; a gang or an Internet newsgroup; an organization like a firm, an administration, or a nongovernmental humanitarian organization; a community like a neighborhood, a local church community, a local business community, or a local ethnic community; or a society like a local society, a national society, a supranational society, for example, European society or even world society.

Actor Integration: Cohesion and Breaking Apart, Integration and Disintegration, Harmony and Conflict

What are the constituent parts of social units? On one level, we can say that these are actors as members of social units like groups, organizations, communities, and societies. On a second level, families form constituent parts of clan societies, estates of estate societies, classes of class societies, functional units of functionally differentiated societies, and organizations of organizational societies; groups and divisions are second-level constituent parts of organizations. What is then the extent and intensity of interlinkages between the constituent parts of a social unit? With regard to members of social units as individual actors or corporate actors (groups, organizations, communities, and national societies within world society), it is the number of actors involved in recurrent interaction (extent) and the frequency of interactions (intensity). Such interactions can be more or less harmonious or conflictual. Actors can be extensively and intensively linked by conflict. For example, a couple could live in war from marriage to death. Such a case would be covered by the thus far outlined definition of social integration. Yet, there must be stronger forces of attraction that keep them together than just forces of repulsion (Simmel, 1908/1992, pp. 312–315; Coser, 1956, pp. 81–85).

Here, we enter the field of explaining social integration. One explanation is that they are linked together because both of them have either no alternative at all or alternatives that are too costly so that transaction costs would be too high. For reasons of clarity, we can use the term 'cohesion' in order to denote a type of relationship between the members of a social unit that entails extensive and intensive interlinkage, as there are more forces of mutual attraction than of mutual repulsion. The opposite of social integration is not conflict but social disintegration; both are the extreme poles of a continuum with many gradations in between and a middle zone where it is difficult to precisely determine where integration ends and disintegration begins. We can say that a couple is more integrated the more they share a common life together and the more their action is mutually supportive, and it is more disintegrated the less this is the case. Just as integration has its opposite in disintegration and not in conflict, so conflict has an opposite of its own, namely, harmony. Conflict means that with two or more actors, one actor's gain implies the other actor's loss. They may have different goals that cannot be attained at the same time, or they may have the same goal, which, however, cannot be reached by every actor at the same time. Harmony, instead, implies that every actor's goal can be realized at the same time or that one and the same goal can be reached by every actor at the same time.

Action Integration: Negative and Positive Integration

A more ambitious notion of social integration is at stake, when we look at not only the integration of actors as members of social units, but also the integration of their actions. This is a second step in defining social integration. The integration of actions can be realized in two ways: negatively and positively. The negative way avoids the actions interfering with each other. The ideal-typical case of this integration of actions is embodied by two farmers who live on their own on their demarcated territory with guarded fences so that there is no chance of intrusion in either's domain of freedom. This kind of coordinated freedom can be called negative freedom. It is a freedom that results from preventing others from intruding in one's domain of free action. The corresponding type of integration can be called 'negative integration.' Durkheim used the term 'negative solidarity' for that (Durkheim, 1964). It refers to the mutual acknowledgment of property rights. In the case of negative integration, the actors do not need more than the acknowledgment of their freedom to act by other actors, they do not require their cooperation and support.

The counterparts to negative freedom and negative integration are positive freedom and positive integration, which explicitly rely on mutual cooperation and support (Durkheim, 1964). The most elementary form of positive freedom can be

found in market exchange. As Adam Smith (1937) demonstrated, the utility maximization of one actor does not occur at the cost of other actors here, but even furthers the other actors' own utility maximization. In the founding years of sociology, it was Herbert Spencer (1972) who promoted this idea. The actors are not engaged in a zero-sum game, but in a game with a growing sum of which potentially every actor can make a profit. Their actions are in a complementary relationship to each other. Both exercising negative freedom on one's own space without interference from others and positive integration through market exchange are only possible if the actors share a minimum of rules of the game; otherwise they would end up in struggles for advantages by unlimited means including force and fraud, the Hobbesian war of all against all (Hobbes, 1966). The question is then how it is possible that free actors come to share a minimal set of rules of the game. In a first step, cooperation in market exchange might rely on the human individual's sympathy for other people as Adam Smith, as well as David Hume, assumed (Smith, 1966; Hume, 1777/1980). However, this sympathy mostly does not reach beyond particular communities and does not always guarantee the commitment to the rules of the games. Therefore, there is a need for further arrangements. Here the notion of 'positive freedom' becomes relevant. We move from the Scottish moral philosophers' individualistic theory of market integration to Rousseau's collectivistic theory of integration by the general will based on the republican spirit of citizens (Rousseau, 1973). A further tradition of thought, which takes on significance here, is German idealism. It was founded by Fichte, Schelling, and Hegel in response to Kant's critical philosophy and carried on in transformed ways by Marx and his followers right through to critical theory and Habermas' theory of communicative action (Kant, 1956; Hegel, 1965; Marx, 1962; Habermas, 1984, 1989).

Social Integration and Social Order

At this stage of treatment of social integration, social integration comes close to social order as soon as one asks for the integration of free action and of rights to act. Integration and disintegration then correspond to the pair of order and disorder or anomie in Durkheim's terms (Durkheim, 1964). From this viewpoint, the actions of individuals are integrated, in as much as everybody can rely on normative regulations that determine the space of their actions so that negative interferences are avoided. Social order of this kind is a normative order, as Talcott Parsons has emphasized in particular (Parsons, 1968). It is based on processes of regulation through collectively binding decision making. Its opposite, disorder or anomie, means that individual actors cannot count on such regulations when they encounter other actors and thus have to rely on the power available to them in order to defend their claims for space for action. As everybody has to do so, there is always the danger of the Hobbesian war of all against all.

If actors and groups are free to articulate interests within a wide framework of constitutional rules, and if the actors see themselves dependent on the tolerance and/or cooperation of the other actors, they will engage in bargaining processes in which actors look for the maximization of their interests. Such rules will have better chances of survival, which allow for the growing satisfaction of a growing number of interests. Here the actors conceive of themselves as utility maximizers who learn to cooperate in a way that is beneficial for all. This is how the evolution of cooperation is explained from the point of view of utility maximization. This order is an ongoing process of steady change that serves for one interest some time and another interest at another time, or better, an always changing mixture of them. The evolutionary explanation of social order in economic terms has been particularly demonstrated by Robert Axelrod (1984). Generally speaking, this tradition of thought in sociology goes back to Herbert Spencer (1972) and is represented in contemporary sociology, for example, in the works of George C. Homans (1974), Michael Hechter (1987), and James Coleman (1990). The basic paradigm is rational choice theory. There have been many attempts to transcend the limits of economic thought, beginning with the classics, particularly Adam Smith in his work on moral sentiments (Smith, 1966). One of the more prominent recent attempts is Jon Elster's acknowledgment of the noneconomic, in his view nonrational, emotional sources of norm-regulated behavior (Elster, 1989).

However, there are also other settings that exert a different shaping influence on the emergence and continuation of social order. There may also be unbridgeable conflicts between the goals of major actors. In this case, social order is an outcome of a power struggle with winners who shape social order by their ideology and impose that order on the defeated through the application of monopolized physical force. This is what Dahrendorf (1958) has emphasized in his conflict theory of social order. A more complex model of conflict theory for the explanation of social order, which includes negotiation and ritual, has been constructed by Randall Collins (1975).

A completely different setting is given, when there are well-established institutions of discursive reasoning and professional legislation in the hands of legal and other types of experts. Both interest negotiation and power struggle have a more limited space for influencing the emergence and continuation of social order. This process takes place much more as the steady building up of an all-embracing, consistent, coherent, and detailed set of laws. The major question, which decides on the success of a certain proposal of legislation, is not so much as to what interests are served and what power can be mobilized, but as to what good reasons can be given and as to how it fits in the existing system of law. This type of social order is a steadily growing legal order that covers almost everything that changes in an ongoing process of adjustments to new problems and challenges. In this perspective, we conceive of social order as a norm-building process. There are different approaches to addressing this problem. The tradition of German idealism sees norm building as a process of meaning construction. The modern version of this approach is Habermas' (1984, 1989) discourse ethics, which explains norm building as a procedure of rational argumentation. Another perspective of relevance here is phenomenology as developed by Schütz (1964), Berger and Luckmann (1966), and others. Here, norm building is conceived of as a process of

institutionalization through habitualization, sedimentation, and traditionalization, as well as legitimation from rudimentary explanations to generalized symbolic. From the point of view of Harold Garfinkel's (1967) ethnomethodology and related conversational analysis, normative order is an ongoing process of ordering through the concerted action of individuals in their respective situation. For symbolic interactionism as promoted by Herbert Blumer (1969) – based on the work of George Herbert Mead (1934) – and by Anselm Strauss (1978), for example, order is negotiated in processes of mutually fitting different perspectives on the situation. In the pragmatist perspective developed in the works of William James, Charles Sanders Peirce, John Dewey, and George Herbert Mead, and revitalized by Hans Joas, order is produced and reproduced by the creative acts of individuals who cooperate in the solution of problems (Joas, 1992).

A further factor that exerts an influence on the emergence and continuation of a social order is the building of relationships of solidarity in the sense of mutual support and help. The breakdown of the traditional order and its hierarchical system of privileges for estates was partly caused by the lacking inclusion of the rising bourgeoisie according to its contribution to the working of the society, particularly in terms of tax payments. There was a new class that was inadequately included in the participation in associational, political, and cultural life. The bourgeois revolutions established a new form of inclusion, which was much broader. Inclusion was no longer based on inherited status, but simply on achievement (particularly in terms of market income, but increasingly also in terms of education and professional status). This new form of inclusion served as the door for every further movement aiming at the participation in economic, political, associational, and cultural life and their organizations. The first one to succeed was the labor movement with the inclusion of the working class; it was followed by different kinds of movements, from the women's movement, the civil rights movement, and the movements for any kind of minority rights, right through to the movements for multiculturalism, prochoice, and prolife. The sociological approach that sees the emergence and continuation of social order particularly as a process of solidarity, civic order and citizenship production, reproduction, and transformation has been founded by Emile Durkheim. This approach is carried on, in particular, in the functionalism of Talcott Parsons and in its contemporary revitalization by neofunctionalism. A further major contribution is T.H. Marshall's work on citizenship (Durkheim, 1893/1964; Marshall, 1964; Parsons, 1971; Alexander, 1998).

The Negative Effects of Social Integration

Social integration is not an overall positive state of affairs. In as much as it is limited to a particular unit below world society, it is always accompanied by at least some demarcation from other social units and corresponding disintegration. In this sense, nation-state disintegration is a precondition for supranational integration. Further on, social integration resides at least to some degree on processes of internal homogenization that may include not only the peaceful merging of different regions, ethnicities, and cultures, but also the imposition of a central culture on peripheral cultures, of the domination of a central ethnicity on peripheral ethnicities, and of a central region on peripheral regions. Instruments for this process of 'internal colonization' are the penetration of the center's language, legal system, bureaucracy, school system, and communication system into the peripheral regions (Hechter, 1975). In this way, social integration levels down differences and thus the richness of cultures and social life as well as the potential for innovation and change. Thus, we can say that a balance of integration and at least some disintegration is a necessary prerequisite for preserving the potential for diversity and innovation. This was particularly emphasized by Emile Durkheim (1982). Simmel (1908/1992) pointed out the interrelation of integration and disintegration, harmony and conflict. Lewis Coser (1956) and Donald Levine (1980) revitalized this contribution by Simmel emphatically.

Social Integration and Systems Integration

Social integration becomes increasingly complex and increasingly requires a balance with elements of disintegration the more one proceeds in the evolution of human societies. Clan societies in the early stages of sociocultural evolution are integrated by blood and rules of intermarriage. Traditional estate societies are integrated by every estate serving a specific function for the living of the whole and the attribution of privileges according to the inherited status. Cohesion and the integration of actions are promoted by the hierarchical order of inherited ranks (Weber, 1976; pp. 133–135, 148–155). Modern societies are integrated in a much more complex way. Their cohesion is based on comprehensive inclusion according to achievement and the constitution of citizenship with civil, political, social, and cultural rights as an abstract community beyond any primordial ties of ethnicity, color, gender, or any other kind of group.

Beyond social integration, modern societies are systemically integrated in as far as they have established functionally specified systems like economy, polity, law, science, education, the media, arts and literature, or religion. Money and democratically legitimated political power are examples of media of communication that serve as means of systemic integration in as much as they allow for the coordination of extremely differentiated economic interests or political goals, irrespective of time, place, and persons involved (Lockwood, 1964; Luhmann, 1988).

In the process of globalization, the functionally specialized systems increasingly reach beyond the nation-state with its relatively strong social integration and produce a world society that is much more integrated systemically than socially through solidarity production and a binding social order (Luhmann, 1997). It is disputed whether one approaches worldwide systemic integration without social integration or whether there is a necessity and also a chance of a subsequently growing social integration on the supranational and even global levels. If we understand social integration in terms of the relatively strong positive integration of the nation-state, there are little chances for social integration on the supranational and global levels. If we realize, however, that this process involves a transformation

of social integration in terms of farther-reaching and internally more differentiated solidarity of networks instead of homogeneous social units, which is accompanied by a corresponding abstraction and formalization of justice, we can imagine that supranational and global systemic integration can still be complemented by social integration.

Social Integration Beyond the Nation-State

A new level of inclusion has now been achieved in the process of transcending the system of nation-states by supranational units like the European Union (EU) or even the United Nations. A major driving force behind this transformation of social integration is the international division of labor. In Emile Durkheim's terms, the shrinking of distances through population growth, and, in the highly developed regions, much more through the increasingly faster methods of transport and communication, is the major force that promotes the growing division of labor (Durkheim, 1964). In this situation, competition for scarce resources intensifies and leaves specialization as the only effective means of escaping the struggle of all against all, besides suicide or emigration, which are, however, less attractive for people who love their lives and their country. Emigration is also only effective for people in poorer regions yet ever less feasible because of the crowding of the economic centers. The change from nation-state inclusion to European and worldwide inclusion is a further step from mechanical to organic solidarity in Durkheim's view. The high level of equality of results in the European welfare states can be interpreted as the most advanced level of founding the organic solidarity of labor division on much reconstituted mechanical solidarity within the boundaries of the nation-state. It reserves the equality of results for natives and excludes people in the poorer regions from its accumulated wealth. In Max Weber's terms, in-group morality and out-group morality are strictly differentiated (Weber, 1923; pp. 303–304). Within the boundaries of the EU, this differentiation is fading and being replaced by one comprehensive morality that is now less substantial and concrete and more formal and abstract justice as fairness within and beyond the boundaries of the nation-state (Münch, 2010, 2012).

The question as to what organic solidarity is and how it is constituted is, however, difficult to answer (Parsons, 1967). First of all, it consists of commitments between individuals who gain in independence from their collective of origin – family, class, and nation – through specialization and growing ties of exchange beyond group boundaries. The farther their relationships reach beyond group boundaries and the greater their number, the more they attain autonomy. Pioneers of cross-border networking exert pressure on less active people to follow in their footsteps, because the commitment to one's group of origin does not offer security any longer, and because claims to loyalty and support by that group appear no longer legitimate in the context of growing cross-border exchange and shrinking in-group ties. In a self-strengthening process, the pioneers create cross-border networks of autonomous individuals while, at the same time, older collective solidarities become weak and fragile.

While classic industrial workers were supported by their class and its representation by trade unions and labor parties, far better educated employees become entrepreneurs themselves, who have to invest in the growth of their human capital. Lifelong learning is crucial for improving one's returns on investment (Pongratz and Voß, 2003; Bröckling, 2007; Jakobi, 2009). The inclusion of the entrepreneurial individual in society beyond national borders does not depend on the solidarity of families, classes, or nations any longer, but on the openness and differentiation of the network woven by the international division of labor. Exclusion in terms of lacking access to markets, wealth, and recognition does not affect whole classes, but marginalized individuals. These disadvantaged people cannot improve their position through collective action, but only through likewise individualized forms of coping with their situation such as, for example, through measures of retraining, further education, self-help groups, or drifting toward various forms of retreat from social life. Collective action against exclusion is totally fragmented. It does not unite people across different situations of frustration. Global movements like criticism of globalization and Occupy Wall Street, on the one hand, lack coherence, endurance, and a forceful idea of reform. National movements, on the other hand, are backward oriented and try to revitalize a collective solidarity that has faded away already.

According to Durkheim, 1964, cross-border economic exchange and division of labor serve as a kind of material infrastructure from which ties of transnational solidarity can emerge. Yet, this needs further supporting devices. Within the nation-state, the control of economic competition and exchange by occupational groups was such a device for him. We can say that the collaboration of the government, employer federations, and trade unions in the national welfare state created a kind of corporatist capitalism that kept economic growth and social integration balanced and came close to Durkheim's vision of a socially integrated capitalist society (Streeck, 1999). It was also in line with Polanyi's (1944) idea that the rise of capitalism as disembedding of the economy from moral ties calls for a new re-embedding in such ties in order to restore social integration in the modern capitalist society. Marshall (1964) coined this development in terms of expanding citizenship from civil to political and to social rights. For Talcott Parsons (1971), it was the development of a societal community. Jeffrey Alexander (2006) has continued along this track with his work on the civil sphere as the center of social integration in modern society. International labor division was kept under control by the segmentary differentiation of world society into strong nation-states.

With the liberalization of markets for goods and services, and particularly the liberalization of financial markets, the preconditions for worldwide economic growth have been improved, although the preconditions for social integration have deteriorated. The growth of moral ties beyond the nation-state has not kept pace with the growth of economic transactions. Financial transactions have proceeded even far beyond the production and exchange of goods so that there is not only a growing gap between global economic exchange and global social integration, but also between the exploded financial transactions and actual economic production and exchange. In this situation, transnational financial and economic integration is being accompanied by national

disintegration. While transnational moral ties are growing but remain still weak, national solidarity is eroding (Rueda, 2007; Streeck, 2009; Wacquant, 2008/2009; Palier, 2010). While economic inequality between nations has decreased slightly since 1970, it has increased within nations (Firebaugh, 2003; Alderson et al., 2005; Beckfield, 2006; Bartels, 2007; Hacker and Pierson, 2010). This contrary course of transnational and national integration confirms Durkheim's (1964) statement that growing international labor division reduces differences between nations but increases them within nations because of individual specialization. The latter is increasingly difficult to subject to collective solidarity organized by trade unions. In this process, national collective forces working against inequality and disintegration caused by market competition are weakened (Kim and Sakamoto, 2010).

At this point, we might ask about the chances of reconstituting a kind of corporatist collaboration between governments, employer federations, and trade unions on the international level along the lines of Durkheim's and Polanyi's argument that the capitalist economy needs to be embedded in ties of solidarity in order to keep its socially destructive forces under control. In fact, the growth of cross-border economic transactions has been followed by increasing international activities of governments and nongovernmental organizations in regulating the economy (Boli and Thomas, 1999). The World Trade Organization is expected to keep free trade and the working of national economies balanced. The International Labor Organization is committed to the institutionalization of basic rights of employees everywhere. An enormous number of international nongovernmental organizations (INGOs) are devoted to promote the respecting of human rights all over the world. Multinational corporations are under the observation of INGOs with regard to their compliance with standards of employee rights and ecological balance (Curbach, 2009). In order to demonstrate their willingness to cooperate, they have engaged in self-regulation such as the global compact for realizing basic rights of employees worldwide. Corporate social responsibility has become a major device in the struggle for global recognition (Hiß, 2006). However, this follow-up growth of the moral regulation of global economic competition is far behind the level that had been attained by the national welfare state.

Not even the most advanced supranational political unit – the EU – has been able to reconstitute social integration on the Union level. According to the neofunctionalist theory of integration, growing economic integration is expected to spill over to legal and political integration (Haas, 1958/1968). This is close to Durkheim's thesis that international labor division creates the tracks along which organic solidarity may advance (Durkheim, 1964). In fact, the history of the EU shows increasing legal and political integration at an accelerating pace since the mid-1980s (Fligstein and Stone Sweet, 2002). The Union's legal integration is largely limited to making cross-border economic transactions easier. Its political integration lags far behind the political capacities of the nation-state (Münch, 2001, 2010). Therefore, the EU has still limited capacities to cope with the socially destructive effects of European economic integration and global economic competition. The Economic and Currency Union struggles with the destructive effects of mounting state debts in economically weak member states. As a consequence, there is a large gap between the globally minded elites and the still nationally minded masses both with regard to European and global integration (Fligstein, 2008; Haller, 2008). The elites are advancing transnational integration, while the masses miss the quality of life in security in the transnational context and therefore still expect this security from the nation-state. It is, however, the dilemma of social integration in the multilevel system that transnational integration cannot proceed without some kind of national disintegration and that transnational integration cannot attain the quality of solidarity that existed within the national welfare state (Rodrik, 2011; Münch, 2012).

Abstract

Three assessment approaches, each with different conceptualizations of intelligence and why it should be measured, are reviewed. The defining feature of psychometric assessment is its empiricism. The approach rests on strong method but its theoretical origins are slim. Exploiting both these factors, psychometricians bootstrapped a structure of intelligence model, reduced (sub)cultural bias, and increased remedial utility in these tests. The tests are still criticized, however, for their limited sampling of the intelligence domain. Psychometric tests are good classifiers and predictors in academic and work contexts. Focusing not on what an examinee knows but how he/she reasons, neuropsychological approaches rest on theories of brain function to assess the *process* of cognition. Empirical considerations remain important but are subsumed by theory. Although on introduction these tests had severe limitations, second-generation neuropsychologically based intelligence tests work with improved psychometrics and a better match of subtests to theory. Psychometric and neuropsychologically based approaches are showing a trend toward integration, both in terms of utilizing converging theoretical models and as practitioners increasingly rely on cross-battery assessment. This merged approach appears the way of the future; psychometric and neuropsychologically based frameworks have both demonstrated that they can generate novel findings and seamlessly incorporate new cognitive advances. The third approach, dynamic assessment of intellectual functioning, incorporates varied interactive evaluation procedures to assess and modify learning potential. The strength of dynamic assessment lies in its individualized, remediation-based reconceptualization of intellect and its attention to bias. While ambitious and still widely used, research in the approach is subsiding, as is practice. The dynamic approach will likely fade from mainstream assessment, although its emphases on reducing test bias and targeting remediation will remain a legacy.

Oversimplifying somewhat, there are three applied approaches to assessing intelligence (Daniel, 1997). Each rests on a different conceptualization of what intelligence is and why it should be measured. Each approach, the psychometric, the neuropsychological, and the dynamic, is reviewed below.

In addition, several physiological indices (e.g., brain wave tracings, reaction and inspection times, nerve conduction velocity, rate at which glucose is metabolized in the brain) correlate with intelligence measures (Neisser et al., 1996). However, physiological indices are not reviewed here because they have little applied utility. For example, a quantitative review of 172 studies showed only small to moderate correlations between information processing speed (typically involving reaction time to simple stimuli) and psychometric tests of intelligence (Sheppard and Vernon, 2008).

Psychometric Assessment

The psychometric approach has dominated intelligence testing for a century. The defining feature involves its empirical foundation; 'psychometric' simply refers to the quantitative measurement of psychological states/abilities. While quantitative assessment rests on a massive measurement technology, its theoretical origins are shallow. Contemporary intellectual measures emerged directly from studies by Alfred Binet and colleagues in France. In 1904, Binet was directed to devise a means of distinguishing educable from noneducable students in the relatively new universal education system. Having investigated cranial, facial, palmar, and handwriting indices, Binet discovered that the direct measure of complex intellectual tasks involving judgment, comprehension, and reasoning most successfully distinguished among pupils. Based on these pragmatic beginnings, Binet (1905) defined intelligence as the capacity to adopt and sustain a direction, make adaptations for the purpose of attaining a desired end, and monitor performance self-correctively. With little elaboration, this definition still directs the psychometric paradigm.

Typically, modern psychometric instruments consist of varied subtests that tap diverse aspects of the loosely defined intelligence construct. For example, scales may include subtests that sample a broad range of knowledge (e.g., vocabulary, historical facts) and require the examinee to solve unfamiliar problems (e.g., assemble colored blocks to resemble a prespecified design) (Groth-Marnat, 2009). Again, choice of subtests is not driven by theoretical prescription. Subtests are selected because they work – in combination, they serve to rank individuals according to how much they know and how good they are at solving particular problems. The pragmatic selection of subtests is based on Binet's (1905) broad definition of intelligence and Spearman's (1904) conception of intelligence as a general or undifferentiated ability (*g*); in principle, the tasks that tap *g* are interchangeable (Mackintosh, 2011).

At the heart of psychometric testing lies norm referencing (Urbina, 2011). Norm referenced tests are developed by administering items in a standardized manner to a representative sample of the population. The normative sample is considered 'representative' insofar as it is stratified within age groups for variables that might influence performance differentially, such as sex, geographic region, ethnic status, community size, etc. Scores are scaled such that each individual's derived score represents a relative standing within the normative or standardization group. In this sense, psychometric testing is an empirical endeavor in its purest sense: as a comparative construct, there is little need to theorize about the exact nature of intelligence.

As mentioned, most modern psychometric tests include varied tasks. The original intention was to ensure that *g* was comprehensively surveyed. With time, however, clinicians came to exploit the multitask construction of intelligence tests to make intraindividual comparisons (Urbina, 2011). By looking at the variability among subtests or groups of subtests, assessors hypothesized about the examinee's relative intellectual strengths and weaknesses. For example, a particular respondent might prove better on tests of verbal comprehension than on tests involving memory. It is important to note, however, that the analysis of intraindividual differences developed after the fact; such comparisons are driven by the practicalities of what subtests are available.

The empirical base of the psychometric effort implies both strength and weakness. The central strength involves its emphasis on reliability and validity of test scores. 'Reliability' refers to consistency of measurement; the more reliable a measure, the less error involved in estimates derived from it. Many psychometric tests boast extremely high internal reliability (the degree to which each component score of the test correlates with the full test score) and 'test–retest' reliability (an index of stability derived by administering the test to the same sample of individuals more than once). Short-term stability of composite scores typically exceeds 0.90 and can show reasonable stability over a 20-year time span (Groth-Marnat, 2009). The validity of these tests, too, has proven strong (Gottfredson and Saklofske, 2009). 'Validity' refers to the extent to which a test measures what it is designed to measure. Intelligence test scores correlate with the amount of schooling, quality of work produced in school, occupational status, and performance in the work situation, both concurrently and predictively (Gottfredson and Saklofske, 2009). Intelligence tests are also sensitive to neuropsychological deficit (Groth-Marnat, 2009) and, perhaps because life requires continual learning and reasoning, intelligence is related to accidental injury, lower adherence to medical treatment, preventable chronic illness, and premature death (Gottfredson and Saklofske, 2009).

The atheoretical, empirical approach central to psychometric testing, lies at the heart of many test shortcomings. Ironically, however, this same atheoretical, empirical base confers an elasticity that permits adaptive change via renewed test content, testing procedures, and test development/revision strategies, all designed to attenuate test limitations.

To exemplify, the interpretation of intraindividual differences is often emphasized over full-scale score, although the latter is the most reliable and valid indicator in any intelligence test (Gottfredson and Saklofske, 2009). As mentioned above, subtests are pragmatically chosen and the implications of subtest variability are rarely validated empirically. Furthermore, the atheoretical approach to task selection has resulted in restricted and incomplete sampling of the intelligence domain. For example, it has been argued that intelligence tests neglect musical and interpersonal abilities (Chen and Gardner, 2012; Sternberg, 2012) as well as vital cognitive domains such as rational thinking (Stanovich, 2009) and learning potential (Feuerstein et al., 1979).

Despite the pragmatic selection of subtests, however, post hoc analyses of intelligence and other cognitive data reveal that they converge in remarkably similar ways across tests and studies (Schneider and McGrew, 2012). Three hierarchical strata of intelligence have been identified in what is called the Cattell–Horn–Carroll (CHC) theory of intelligence. The CHC model is one of the most important developments in over a century of intelligence testing (Schneider and McGrew, 2012), providing, as it does, an empirically and theoretically convincing model of the structure of intelligence. At the highest stratum is a general factor, *g*. This factor subsumes a second stratum of broad factors, including 'fluid' and 'crystallized' intelligence. Fluid intelligence involves the ability to cope with novelty and think flexibly. Crystallized intelligence involves the storage and use of declarative knowledge such as vocabulary or information. Subsumed under each broad factor is a set of narrow abilities, such as 'induction' and 'reading comprehension.' The CHC model has proven applicable across all ages, sexes, races, and cultures evaluated thus far (Gottfredson and Saklofske, 2009). As such, it assists in interpreting intraindividual cognitive variability. Furthermore, the model could be used to inform one about important vectors neglected by extant intelligence tests (Schneider and McGrew, 2012). The CHC model exerts a profound influence on test construction/revision while imposing little restriction on the type of tasks that can be incorporated into intelligence tests.

It remains true, however, that while psychometric testing has illuminated the structure of intelligence, the CHC model provides little insight into the meaning of intelligence (Urbina, 2011) or the operations, processes, and mechanisms that underlie it (Mackintosh, 2011; Sternberg, 2012). In part, psychometricians circumvent this imperfect comprehension by assessing intellectual function with reference to a norm group; the question an assessor asks is not 'how intelligent is this person?' but 'how well does this person perform compared to other people who are like him/her in important demographic respects?' However, this gives rise to questions about bias because (sub)cultural, ethnic, life-experience, and motivational differences could render the standardization sample unrepresentative of any given examinee. This is not to say that the construct of *g* is false, but that a given item/subscale may not tap into *g* equally for all individuals. This becomes a social issue when examinees from minority groups are compared to a norm sample whose context, values, and learning experiences are different from their own. Testing thereby betrays its original purpose of providing objective data on an individual's intellectual functioning and comes, instead, to discriminate against atypical examinees. While this issue has historically plagued test construction, contemporary test developers typically incorporate a panoply of bias-mitigation procedures, including improved standardization sampling, increasingly sophisticated statistical approaches to bias detection, minority stakeholder reviews, reduction of language demands, and assessment of examiner and examinee features that may influence test performance (Gottfredson and Saklofske, 2009).

Another difficulty with psychometric tests is that, although they usually correlate highly among themselves, this is not always the case. Correlations may be influenced by what tasks are included and how they are weighted. Perhaps a greater problem lies in the fact that even where test scores do correlate highly, the same individual may earn discrepant scores on different instruments because tests are normed on different

standardization groups and at different times. These issues are not entirely resolvable, but improved norming standards and increased understanding of the structure of intelligence, as provided by the CHC model, will likely attenuate these differences (Gottfredson and Saklofske, 2009).

A crucial criticism of psychometric tests is that recommendations derived from these instruments have not been shown to enhance remediation for the examinees (Feuerstein et al., 1979). Again, this can be attributed to the fact that the content of these scales has not been selected according to any theory of intelligence, brain functioning, or pedagogy. Nevertheless, some test developers now incorporate companion guides into their test kits that address the issue of test-based intervention directly (Truch, 2006), although research in the area remain sparse.

To summarize, although there are limitations to psychometric measurement, the approach yields reliable and valid estimates of intellectual functioning. Psychometric tests are accurate classifiers and predictors when used with care in appropriately circumscribed contexts. The empirical nature of the psychometric approach permits flexibility in test improvement, such that the limitations discussed above are theoretically tractable. The CHC model provides insight into the latent structure of intelligence, informing test development without imposing undue restrictions, while the empirical foundations of the approach permit development and refinement of items/subtests that incrementally improve test properties. A century of research on the psychometrics of intelligence amply confirms an early assessment of the field: "simply … measuring promiscuously any large number of different abilities and pooling the results together …, which might seem the most arbitrary and meaningless procedure imaginable, had really a profound theoretical basis and a supremely practical utility" (Spearman, 1930).

Neuropsychologically Based Assessment

The neuropsychological approach to intellectual assessment is represented by several theory-based tests that were developed in reaction to the pragmatics of psychometric assessment. The neuropsychological approach, emerging in the 1980s, reflects an attempt to increase the validity and utility of assessment by basing it on an understanding of brain function and brain–behavior relationships. The emphasis is not on what the examinee knows but on how the examinee reasons; not on observable abilities but on underlying capacities (Sparrow and Davis, 2000). Repudiating the psychometric emphasis on *g*, neuropsychologically oriented test construction operationalizes the notion that the brain is composed of interdependent but separable functional systems (neuromodularity).

First-generation neuropsychological approaches to intelligence testing were almost exclusively influenced by the theories of Alexander Luria (1980), a Russian psychologist. Luria proposed three levels of brain functioning that mediate distinct types of learning and performance. The first, attention, involves selectively attending to particular stimuli while inhibiting attention to competing stimuli over time. Attention is assessed with tasks that demand sustained concentration on one stimulus and sustained inhibition of response to distracting stimuli. The second functional unit involves encoding and processing information. According to Luria, information can be processed simultaneously and/or successively. Simultaneous processing is holistic; it involves organizing stimuli into interrelated groups. Simultaneous processing can be assessed with tasks that require an examinee to recall the spatial locations of stimuli, and construct abstract designs from several identical triangles. Successive processing involves integrating stimuli serially, such that each stimulus is related to the one that precedes and follows it in chainlike succession. Successive processing can be tested with tasks requiring, for example, that the respondent repeat numbers spoken by the examiner or repeat an ordered series of hand movements made by the examiner. Planning and monitoring functions form the third and highest cognitive level, according to Luria. This involves the integration of attention and simultaneous and successive processing, along with acquired knowledge, to permit the formation and execution of plans and ongoing verification of their efficacy. Neuropsychological tests of intelligence include subtests that assess such processes. These scores can be compared to derive a profile of strengths and weaknesses, which, in turn, has direct educational implications. It is also important to note that psychometric considerations such as reliability, validity, and norm referencing are stressed, but they subserve theoretical relevance (Kaufman, 2000).

Second-generation neuropsychological intelligence tests are based on the elaborations of Luria's theory (Naglieri et al., 2012) and neurocognitive findings on cerebral specialization. Of extreme theoretical import, at least one test (Kaufman and Kaufman, 2004) also incorporates the CHC model, simultaneously measuring performance on the CHC factors and on the levels of brain functioning using largely overlapping subtests. Not all neuropsychologically based test developers adopt this approach (Naglieri et al., 2012), however, suggesting that the field is moving toward a continuum of test options representing psychometric and neuropsychological traditions at the extremes, with hybrid instrumentation occupying a middle ground. Furthermore, this trend is augmented by the increasing popularity of cross-battery assessment, which involves the systematic augmentation of a core test with carefully selected components of other tests to extract psychometrically robust and comprehensive understanding of an individual's strengths and weaknesses. Originally founded on the CHC model, the cross-battery approach was later augmented with neuropsychological theory (Flanagan et al., 2013), further integrating psychometric and neuropsychological approaches to the assessment of intellectual function.

The neuropsychological approach to intelligence testing has limitations and strengths. A central shortcoming of these theory-based tests lies in the speculative nature of the theories upon which the tests are based (Gottfredson and Saklofske, 2009). This is compounded by controversy regarding whether test components actually measure the theoretical constructs they purport to measure. This is particularly true where the same subtests are used to represent both levels of brain processing and CHC factors (Mays et al., 2009), contributing some ambiguity to their interpretation. Resolution of issues pertaining to 'construct validity' (whether a test measures what it purports to measure) is crucial.

What of test bias, as discussed in the context of psychometric testing? Although the neuropsychological approach focuses aggressively on minimizing discrepancies between whites and minority groups, early attempts worked by sacrificing breadth of intellectual sampling (Urbina, 2011) and minimizing differences artifactually. However, recent efforts employing psychometric technologies such as listed above show that it is possible to reduce racial discrepancies legitimately, but not necessarily to eliminate them. These discrepancies indicate the need for judicious use of testing and appropriate advocacy for resource allocation to disenfranchised populations.

It has been argued that the theoretical underpinnings of neuropsychological tests of intelligence both restrain and augment the breadth of subtest selection (Das et al., 1994). Which perspective one takes depends on the neuropsychological test one is considering and what one considers the purpose of testing to be. It is true that such tests neglect areas of intelligence such as creativity and wit, but the purpose of these new instruments is primarily to aid in pedagogic planning. Hence, it is the insight these tests afford into a given examinee's strengths and weaknesses with respect to learning that is important, as well as the remedial implications of the testing. Although further research is needed, preliminary evidence indicates efficacy in both these domains, with carefully controlled trials showing hypothesized gains in prespecified areas (Naglieri et al., 2012). For example, students with poor planning improved dramatically in math calculation when instructed in the use of strategies; other students who were good in planning showed more modest improvements when instructed in the use of strategies.

In the past, it has been argued that if these instruments prove successful in directing effective pedagogy (Atkinson, 2001) and if they are seen as more than just alternative or adjunctive to psychometric measures (Sparrow and Davis, 2000), they will have addressed the major shortcoming of psychometric assessment without sacrificing its empirical strengths. These are high standards and, although more research is needed, it is fair to say that these standards are in the process of being met.

Dynamic Assessment

Incorporating a heterogeneous set of evaluation procedures, the defining feature of dynamic assessment is that it evaluates and modifies cognitive functioning simultaneously through mediation and intervention. The product of a dynamic assessment is not an estimate of the examinee's intellectual standing relative to their peers, but an estimate of learning potential. The notion behind the learning potential construct is that individuals with similar starting competencies (e.g., similar IQs) may respond differentially to instruction; what an individual has learned does not necessarily reflect the individual's potential to learn (Grigorenko and Sternberg, 1998). Some theorists equate learning potential with *g* (Fabio, 2005), although they emphasize that *g* is mutable through training (Corman and Budoff, 1973). Dynamic assessment represents a reaction against psychometric testing in particular, with its purported overreliance on previously learned material; neglect of process in favor of content; failure to consider factors other than ability in measuring IQ (e.g., the (sub)cultural, motivational, personality, and social adequacy differences in examinees); and irrelevance to remediation (Fabio, 2005). The theoretical writings of Lev Vygotsky, a Russian psychologist, form the context of dynamic assessment. Vygotsky (1987) argued that what a child can accomplish when assisted by someone more knowledgeable ('zone of proximal development') is more indicative of the child's mental development than what the child can do alone ('zone of actual development'). The zone of proximal development is operationalized in dynamic assessment as a 'mediated learning experience' (Feuerstein et al., 1979) by a collaborative examiner (a 'mediator,' in dynamic parlance). The mediator provides ongoing feedback, titrated such that it is just beyond the examinee's zone of actual development, until the examinee either solves the problem or gives up. Thus, testing and teaching are joined. This is facilitated by emphasizing tasks that stress fluid rather than crystallized reasoning skills. The Vygotskian basis of dynamic assessment is supplemented by information processing concepts in some dynamic approaches. For example, one approach stresses the central role of working memory, the ability to hold old and new information in memory simultaneously, so as to manipulate and transform it (Campione and Brown, 1987). Dynamic instrumentation often includes standardized psychometric tasks, as described above, but they are administered interactively.
